

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

### Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

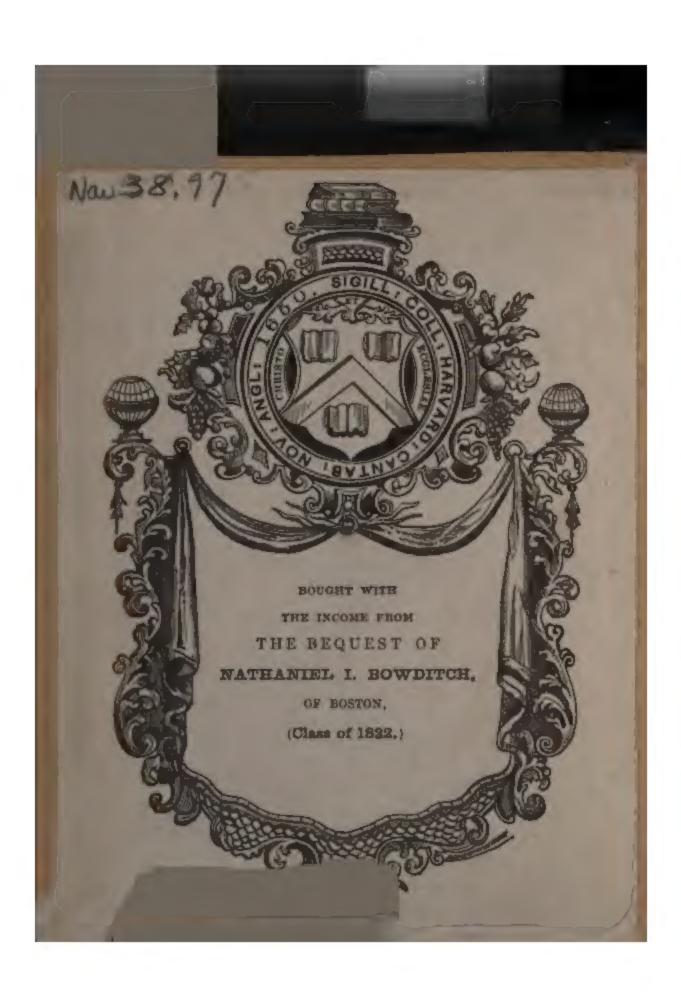

We also ask that you:

- + Make non-commercial use of the files We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + Refrain from automated querying Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + Maintain attribution The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + Keep it legal Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

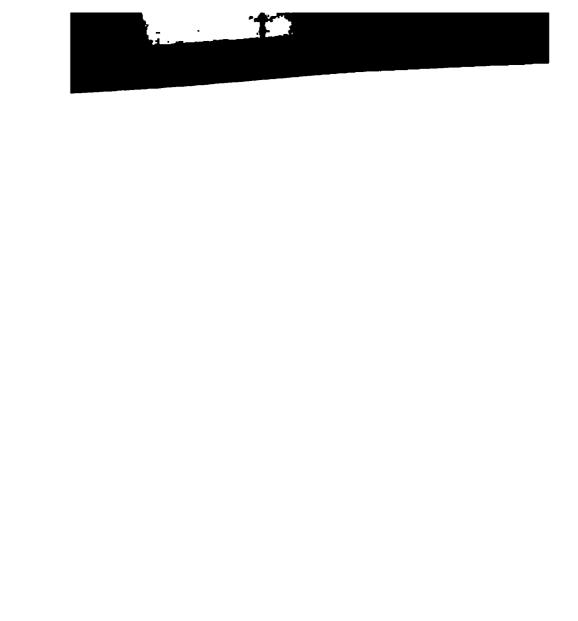

#### About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at http://books.google.com/

# CLOSSARY OF NAVICATION

# A VADE MECUM FOR PRACTICAL NAVIGATORS

BY THE

REV. J. B. HARBORD, M.A., R.N.,

FOR MANY YEARS EXAMINER IN NAVIGATION AND NAUTICAL ASTRONOMY UNDER THE SCIENCE AND ART DEPARTMENT.

Third Edition, Achised and Enlarged.

EDITED BY

H. B. GOODWIN, M.A., R.N.

### PORTSMOUTH:

GRIFFIN & CO., 2, THE HARD.

(Publishers by Appointment, to H.M. The Queen.)

PRINTED AT THE OFFICE OF THE PUBLISHERS 2, THE HARD, PORTSMOUTH.

### PREFACE TO THIRD EDITION.

In the year 1895, I was honoured by the late Mr. Harbord, with an invitation to join him in the revision of his Glossary, with a view to the publication of the present edition.

Before, however, working in concert, we had effected much progress, Mr. Harbord was compelled by the development of the malady that was destined to cut short all too soon a very useful and honourable career, to desist from his labours, and it was left to myself to finish the work alone.

In this task I have been greatly assisted by the copious and valuable notes which Mr. Harbord left behind, arranged with all that scrupulous attention to order and method which had distinguished him throughout his life. While then it would be presumptuous to hope to have removed all traces of the lack of the author's personal supervision, the loss of it will perhaps be less noticeable than would otherwise have been the case.

Many new articles have been added, and some of the old ones re-written, and no effort has been spared to bring the book thoroughly up to date. It is anticipated therefore with some degree of confidence that the book will retain the high position in the estimation of the nautical world, which it first won for itself nearly thirty five years ago.

Should this expectation be realized, the third edition of the Glovery will serve a double purpose, in that, while continuing to promote a sound knowledge of the principles of the sciences of which it treats, it may at the same time serve as a memorial of the industry, learning and ability of the author, who has but lately passed from our midst.

H. B. G.

Greenwich, March, 1897.

### PREFACE TO THE SECOND EDITION.

The Second edition of this little book was drawn up expressly for the young officers of the Royal Navy; and I then stated that my object was to keep them, in what I knew by experience they considered the most troublesome part of their studies. In my preface I wrote as follows - "The author would give this help by teaching them to regard scientific and technical terms not as necessary evils, but as very useful servants, by the rational use of which a definiteness of conception may be acquired not otherwise attainable. It is also his hope in some small measure to aid in banishing a prevailing looseness of phraseology, and in bringing about a consistency of usage in nautical terms." In this object I was greatly assisted by my college mend, the late Mr. Hugh Godfray, who expressed his opinion thus :-"Nothing stands more in the way of a student's real progress than loose notions in the early stages of the subject he is attacking, sitanugh such loose notions are often the natural result of loose wording on the part of the author."

this second and enlarged edition is intended for more extended circulation, and it is boped that it will be found useful not only to the others of the Royal Navy, but to those aspiring to or actually in command if vessels in our Mercantile Marine, and to those enlightened and enterprising gentlemen whose love for the sea has covered it with Yacht Squadrons. To all I would repeat the above counsel; and Litter, I would add some words of Admiral Shadwell, which embody the true method of studying Navigation. He writes —"I am glad to see that you deal liberally in diagrams, and give the mathematical kernulæ, avoiding long and tedious verbal precepts. I am fully premaded that our officers with never be properly instructed in Fantical Astronomy until they make up their minds to discard verbal

rules, and to grapple with the formulæ themselves on which they depend." Dr. Woolley remarks:—"Further, I believe it is most important that the memory, always very liable to fail, should have very little to do. A person whose business it is to apply rules of navigation should, at all times, not only work from formulæ, but be able for himself to reproduce these formulæ, or equivalents, from first principles, and in very short time."

Under each term, besides what is necessary to explain it fully in its different bearings, will be found an analysis of what is to be learned on the subject by systematic reading. In the arrangement of the articles the strictly alphabetical order has sometimes been departed from, as regards the subdivisions of a general head, and what appears in each case to be the natural order has been adopted.

In this task of classifying and arranging, I was led to feel the want of appropriate terms for the two great branches of the science of Navigation. This word Navigation has been dethroned from its rightful position, though no usurper has taken its place. It has simply been degraded by modern writers to fill a very subordinate rôle. I have attempted to restore the term to the meaning it had a century ago, when the most scientific book on the subject in the English language was written, and I have uniformly, therefore, used "Navigation" as the generic word, and the two great subdivisions I have named geo-navigation and celo-navigation. Geography, meteorology, astronomy should all be equally regarded as ancillary sciences. Arithmetic, geometry, and trigonometry, serving as the essential basis of the whole, always formed the introductory chapters of the old treatises on Navigation.

There is another word, introduced in my first edition, which, strange say, was not previously found in any English book on Navigation,

viz. "co-ordinates." This appears to have frightened some, who want no new terms to describe what they have themselves thoroughly mastered without them. But its very general adoption in all schools for young officers, and in many books since published, is a complete sindication of the assistance this one term has given to scientific study based on systematic arrangement.

I have retained the derivations of the terms in the present edition. Those who consider this superfluous can pass them ever; but I look upon them as valuable for several reasons; they sometimes explain a word without the necessity of any long description; they make it easy to remember the term; and they frequently embody its history in a manner both interesting and instructive.

The last point brings me to state why some obsolete words have cen inserted, such as "astrolabe," "cross-staff." A sufficient reason might be found in the fact that these words sometimes occur in an other's reading, and that ordinary dictionaries do not afford sufficient adp as to their meaning. But there is another value attached to them. A sations life may deprive him of the refined means of the restion which modern advancement has placed at his disposal, and be may find immediately decompass or sextant. In such circumstances he would find it invaluable to know something of the rude contrivances of early manightors.

Some topics are treated of at greater length than might appear to the same, and may seem to engross more than their share of room, but has been done advisedly. There are some points on which very me pleas are rooms in and some space is necessary as, in such cases, explanation, to be of any use, must be full. The terms "celestial on and "horizon" are illustrations; and special attention has

to be paid to words which have several different meanings, such as, for example, "distance." Again, very contradictory information is given by different authorities on some points, as, for instance, the meaning and length of the "mile." Once more, information stowed away in old magazines and pamphlets, and not generally found in the usual text-books, is given at length; and this must be the excuse for the full treatment, for example, of "Chronometer Diagrams." Finally, a new method which, up to the present moment, can only be read in the brochure of its author, is given at large: I refer to Airy's new method of clearing the "lunar distance." One topic of vital importance has been enlarged upon for many reasons, viz. "Magnetism and Compass Deviation." In dealing with this the chief guide has been found in the memory of Airy's lectures at South Kensington and his syllabus. For important and the latest information on this subject I am greatly indebted to Staff-Commander Ettrick W. Creak, R.N.

I have to return my best thanks to Captain Sir Frederick J. O. Evans, the Hydrographer, for assistance, and to acknowledge the valuable suggestions I have received from Dr. J. Woolley, the Rev. F. Davies, R.N., Mr. H. B. Goodwin, R.N., Staff-Commander T. A. Hull, R.N., and Mr. A. Escott. To Mr. Escott and Mr. G. C. Pulsford I am grateful for the trouble they have taken to ensure the accuracy of the work.

In conclusion, I beg to introduce my book as a confidential and silent friend, that will remove your difficulties without exposing your ignorance.

J. B. HARBORD.

# NORTH CIRCUMPOLAR STAR DISC. 6 Auriga Horizon E W Horizon IIIX ŹIJ N Stor Manutades

### Circumpolar Star Discs.

These represent approximately the positions of the stars within 45° from the poles at any hour of a given day, in any longitude. The observer is supposed to be in latitude 45°.

The outer fixed run of the disc represents the hours of the day; the inner movable run is graduated for right ascensions.

Face towards the elevated pote; and hold the proper discover the head, so as to view it as you would look at the heavens.

### To set the Disc.

Take out of the "Nautical Almanac" the Sidereal Time, which is the same as the right ascension of the mean aun at mean noon at treeswich. This may be obtained with sufficient accuracy, without referring to the "Nautical Almanac," from the following table, which gives the astronomical days when the sidereal time is so many complete hours:—

										October				
3	4.5	31		8	97	21 .	3.4	,	21		50	(1)	20	
9		- 61	May			6 Aug.	15		9	Nov.	21		- 4	Feb.
ă.		73		0		41 .	1.6		20		22		10	41
ы	44	0	Turse			s Sent	17		E	Dell	23		6	March
	1.7		34		**	A Pro	1 . 6	*		ri	- 3	11		

First consider ZN or ZS to represent the meridian of Greenwich. Place adjacent to Z, by turning the disc, the number is dicating the adjacent time just found. Then the disc will represent the position of the justion, at Greenwich mean noon, to an observer on the meridian of Greenwich, in latitude 45°.

Secondly -Arki the time at place to the sidereal time and turn too do till the number, so obtained, on the inner concendingent is. Z. The line will now represent the required position of the heavens at the time, ZN or ZN being the meridian of the place.

By the aid if these discs may also be fromd the time when any ear with a tre region, will pass the meridian above the horizon at lead the transfer

### Equinoctial Star Chart.

At article Lunar Distances will be found a chart which the two circumpolar discs, completes the view of the heave embraces that part of the heavens which extends from the equi to 45° N., and to 45° S. declination, thus comprehending a zone

In using this chart, it should be held above the head so the central horizontal line corresponds with the equinoctial.

.

## GLOSSARY OF NAVIGATION.

### ERRATA.

Page 450 l 3, for "latitudes" read "altitudes."

Page 452 l 13, for "5° 10' W.," read "5° 18' W."

Page 478 l 5 from bottom, for "as" read "cos."

Page 479 l 9 from bottom, for "log b" read "log c."

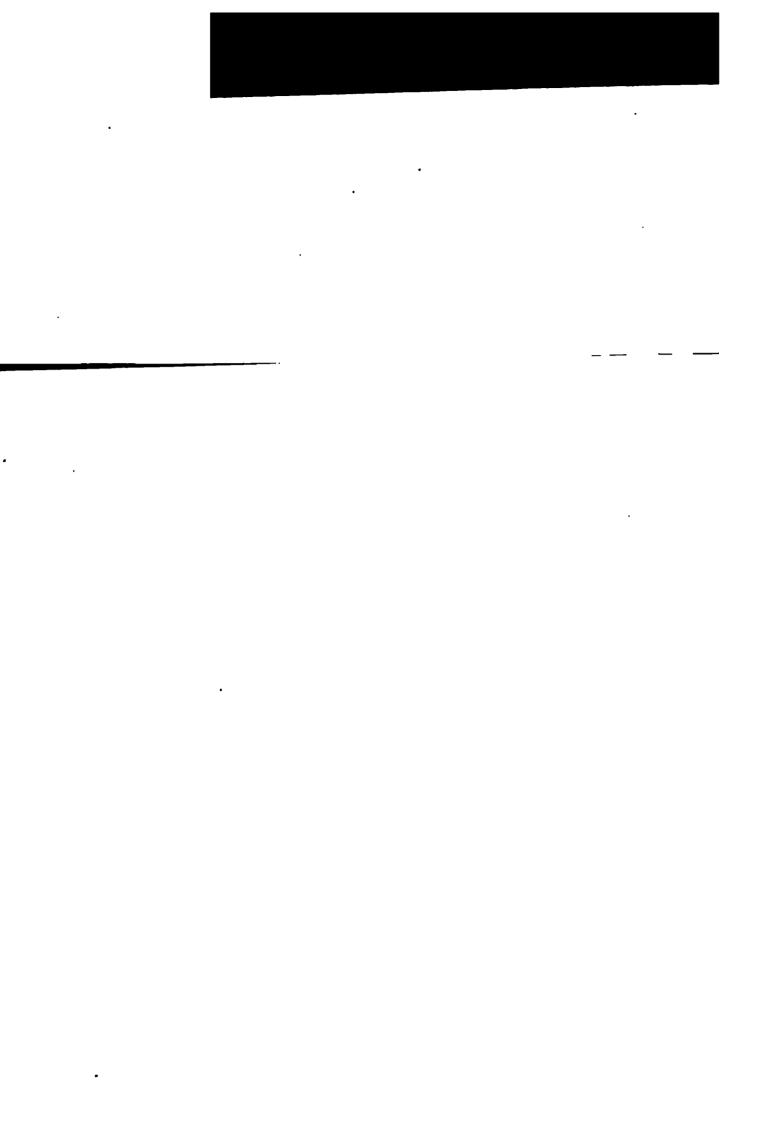

Page 482 l 9, In denominator of fraction for " $\cos \frac{1}{2}(a-b)$ " read " $\cos \frac{1}{2}(a+b)$ ."

Page 483 l 8, for "cos  $\frac{1}{2}$  (A+B)" read cot  $\frac{1}{2}$  (A+B).

Page 484 l 10 from bottom, for " $\pi - a$ " read " $\pi - a'$ "

,, l3, ,, for "b" read "b"

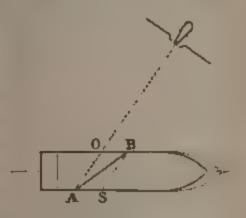

Page 485 *l* 3, 4, for " $\frac{C}{2}$ " read " $\frac{c}{2}$ "

### GLOSSARY OF NAVIGATION.

Aberration (L. aberratio, "a going out of the way").—The disturbance in the apparent direction of an object caused by the combination of its motion with that of the spectator. The following illustration is given by Airy:—If a shot fired from a battery, penetrate the side of a ship in motion and pass out on the other

what and thus it will appear to have been fired from more shead than it was in reality. Let OA and AS represent, in direction and rate, the motions respectively of the object and spectator. Then, in consequence of the motion AS of the spectator, that of the object will appear to him to be in the direction

BA instead of OA; and the angle BAO measures the aberration. The apparent change in the rate BA~OA might be properly called the acceleration. The quantities involved are connected by the relations:

Aberration in Astronomy. The principle explained above

apparent motion of the fixed stars which could not be assigned to any known cause. He ascribed it to the progressive motion of light combined with the earth's annual motion in its orbit. Light is propagated with a velocity of 192,000 miles per second, the earth moving in its orbit during that interval about 19 miles; and the ratio 1 to 10,000 produces very appreciable results. In consequence of the combination of these two things, the light by which a celestial object is seen has its direction apparently changed. This is spoken of as the Aberration of Light, and it causes the apparent positions of objects on the celestial concave to be disturbed. The general result is that all the stars seem to be displaced from their mean positions, towards that point of the heavens to which the direction of the earth's motion tends at any moment; and thus each star will apparently describe, during the year, a small ellipse in the heavens, having for its centre the point in which it would be seen if the earth were at rest. The correction to be applied to the apparent place of a celestial body, consequent upon the aberration of light, is technically called the Aberration. The sine of the aberration is proportional to the sine of the single made by the earth's motion in space with the visual ray, which angle has been called "The Earth's way," The aberration being small, the circular measure may be written for the sine, and we have

Aberration : velocity of Earth . sin (Earth's way) relocity of Light : k sin (Earth's way),

where k is the Coefficient of Aberration and is constant for all bodies seen on the celestial concave. In the case of the moon and planets, which have a proper motion of their own, the light by which the body is seen comes from a point in space which the body no longer occupies when the rays reach the observer on the earth. The result

is generally combined with aberration properly so called, but is more strictly distinguished as the Equation of Light, being the allowance to be made for the time occupied by the light in traversing a variable space. The value of k has been determined from observations made at Greenwich Observatory to be 20" 307. The Correction for Aberration is important in reducing the elements, given in the Nautical Almanac, upon which the navigator depends; but its amount is too small to be taken directly into account, in correcting the observations he himself makes at sea.

Aberration in Meteorology - We propose that the term "aberration" be adopted in Meteorology, in a sense analogous to that which it so conveniently bears to Astronomy The commonest illustration, used to explain the aberration of light, is derived from the phenomenon of drops of rain, which falling vertically on a person at rest, appear to meet him and come down quicker if he runs forward. But the best vindication of this use of the term is found in the history of the discovery of astronomical aberration. Dr. Bradley observed a motion of the fixed stars, which he could not account for by any recognised causes. Annual parallax, the nutation of the earth's axis, refraction, an alteration in the plumbline by which the observing instrument was rectified, were all inadequate. "At last, when he despaired of being able to account for the phenomena which he had observed, a satisfactory explanation of it occurred to him all at once, when he was not in search of it. He accompanied a pleasure party in a sail upon the river Thames. The boat in which they were was provided with a mast, which had a vane at the top of it. It blew a moderate wind, and the party sailed up and down the river for a considerable time. Dr. Bradley remarked, that every time the boat put about, the vane at the top of the boat's must shifted a little

as if there had been a slight change in the direction of the wind. observed this three or four times, without speaking; at last he mentioned it to the sailors, and expressed his surprise that the wind should shift so regularly every time they put about. The sailors told him that the wind had not shifted, but that the apparent change was owing to the change in the direction of the boat, and assured him that the same thing invariably happened in all cases. This accidental observation led him to conclude, that the phenomenon, which had puzzled him so much, was owing to the combined motion of light and of the earth. Since light does not move instantaneously from one place to another, it is clear that a spectator, standing on the earth's surface, will not see a star by means of the same ray of light, if the earth be moving, that he would do if the earth were standing still. . . . . Hence the star will not appear in its true place, but will be seen in the diagonal of the parallelogram, whose two sides are the velocity of light and its direction from the star, and the velocity and direction of the earth in its orbit." (History of the Royal Society, Thomas Thomson, 1812, p, 346).—See Wind, Aberration of.

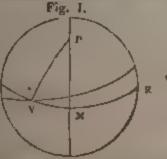

Aberration in Optics.—There is another and a different technical use of the term aberration, also important to those whose calling necessitates the use of optical instruments. In optics, it signifies the deviation of the rays of light from the true focus of a curved lens or speculum, the result being a somewhat confused image of the object.

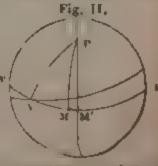

Acceleration (L. acceleratio, "a hastening").—An increase in the rate of motion, such motion in Astronomy being that of revolution. Acceleration is the opposite of Retardation. The rate may be viewed with reference to (I.) the motion of the one body under consideration, or (II.) to the motion of this body relatively to that of others.

- (I.) When one body only is regarded, the acceleration and retardation of its motion are referred to its mean rate. Thus (I) the Planets when moving from the aphelion of their orbits have their motion accelerated, and when moving from the perihelion of their orbits have it retarded; the rate thus oscillating about the mean value: this is spoken of as the Acceleration and Retardation of the Planets. But (2) the mean motion of a revolution or period may itself go through a cycle of change, thus acceleration and retardation being completed after a long lapse of time, centuries or even thousands of years. It is hence distinguished as secular (L seculum" a generation "" an age.") Such is the present increase and future decrease of the mean angular velocity of the moon about the earth, a change spoken of as the Secular Acceleration and Retardation of the Moon.
  - (II) The daily apparent revolution of the stars may be referred to that of the sun. In consequence of the sun travelling in the collection W. to E., while the apparent rotation of the heavens is from E. to W, the stars appear to have a greater diurnal motion than the sun. This is spoken of as the Acceleration of the Fixed Stars. The term retardation would be here applied to the other body, and we might speak of the Retardation of the Sun with reference to the stars.

Acceleration of Sidereal on Mean Solar Time.-The

change of the mean num's right ascension in n mean solar day, in consequence of which, in w the interval of his coming successively to the meridian, day by day

the first point of Aries appears to have hastened forward in its

dirunal revolution; hence the name. To explain this, let MPV (fig. 1) be the sidereal time, when the mean sun is on the meridian of Greenwich on a particular day. When the mean sun comes again to the meridian after a mean solar day, he will have moved in right ascension to the east through MM' say (fig. 2). The sidereal time corresponding to this second mean noon will be M'PV instead of MPV; the first point of Aries thus appearing to have hastened forward in its diurnal revolution, and the sidereal time to be "accelerated" with reference to mean solar time. The angle M'PM, which is the acceleration, is a portion of sidereal time. The amount of acceleration, for any given interval of mean solar time, will enable us to deduce the sidereal time. In the Nautical Almanac, pp. 478, 479, is given a "Table for Converting Intervals of Mean Solar Time into Equivalent Intervals of Sidereal Time." Similar tables are also given in treatises on navigation.—See Retardation of Mean Solar on Sidereal Time.

Achernar.—The Arabic name for the bright star a Eridani.—See Eridanus.

Adjustments of Instruments.—All nautical instruments are liable to get out of order; their several parts not retaining their relative positions, owing to unequal expansion, violence, or like causes. To guard against resulting errors, before observing, there are methods of testing whether the instrument is in order in the several points subject to be affected; and the instrument is provided with means of adjustment, chiefly in the form of screws or sliding weights, by which it may be restored to its correct state. Adjusting screws and weights ought not to be touched more than is absolutely necessary, and then with great care. When two such screws work oppositely to each other, one must not be tightened without the other being previously

nay be acknowledged and allowed for in observing. The term "adjustments" is often loosely applied both to all sources of incorrectness, and the means of obviating their effects, in using instruments. These are, however, properly of three distinct kinds:

(1) Imperfections in the instrument, which should cause its rejection;

(2) Adjustments for parts of the instrument hable to temporary derangement, but which can be restored to order by the machinery attached:

(3) Errors of the instrument, which are acknowledged, determined by experiment, and allowed for. It would be well if the term "adjustments" were always strictly limited to the second of these.

Adjustments of the Azimuth Compass.—The adjustments of the azimuth compass are commonly said to be the following. (1) the "magnetic axis" should coincide with the longitudinal line of the needle; (2) The pivot should be in the centre of the graduated circumference of the card; (3) The "line of sight" should pass directly over the pivot; (4) The eye-vane and object-vane should each be vertical; and (5) The needle, with card, should work upon its pivot horizontally. But of these (1) is properly treated as an error of the instrument and allowed for accordingly; and (2) (3) (4) are imperfections: (5) only coming strictly under the head of an adjustment.

Adjustments of the Sextant.—The adjustments of the extant are -(1) The "index-glass" should be perpendicular to the plane of the are; (2) The "horizon-glass" should be perpendicular to the plane of the are; (3) The "line of collimation" of the telescope should be parallel to the plane of the are; and (4) For distant objects, when the zero of the vermer coincides with the zero

of the arc, the horizon-glass and the index-glass should be parallel. The last is generally, in practice, treated as an error.—See Sextant, Imperfections, Adjustments, Errors.

Age of the Moon.—The "age of the moon" is reckoned from new moon, through a lunation or lunar month, the mean length of which is about 29½ days. It is given in the Nautical Almanac, p. iv., for every mean noon at Greenwich.

Age of the Tide.—The interval between the transit of the moon, at which a tide originates, and the appearance of the tide itself. Called also Retard of the Tide.—See under Tide.

Alamak.—The Arabic name for the bright star  $\gamma$  Andromeda.—Andromeda.

Aldebaran (Arabic, "The Bull's Eye") —The large and bright star, situated in the eye of the constellation Taurus ("The Bull"), in modern catalogues known as a Tauri, but still generally called by its Arabic name, Aldebaran. It is a very important star to the navigator, being one of those whose "lunar distances" are calculated and tabulated in the Nautical Almanac. It is also easily found. The two remarkable groups, the Pleiades and Hyades, at once point out Taurus, and Aldebaran is among the small stars of the latter, conspicuous by its ruddy colour. It is at about the same distance from Orion's Belt on the one side that Sirius is on the other, and a line drawn from the Pole Star a little to the westward of Capella will pass through no great star till it comes to Aldebaran. Mag 1.0. 1896, R.A. 4h 30m, Dec. + 16° 18'.—See Taurus.

Algebraic Signs.—The algebraic signs can be conveniently applied to qualify astronomical and geographical elements which are reckoned in opposite directions from their origin. This enables us to

connect them, in formulæ, with other quantities, without making two cases of the problem. In the Table "Mean Places of Stare," given in the Nautical Almanac, pp. 295-300, north declinations are marked +, and south declinations are marked -..."

Algenib.—The Arabic name for the bright star γ Pegasi.—See Pegasus.

Algol.—The Arabic name for the bright star β Pereci; also known as β Medusæ. It is remarkable as being a "variable" star, changing from the second or third magnitude to the fifth in the period of 24 20% 50m.—See Perseus.

Alioth. The Arabic name for the bright star Capella, a

Almacantars, Almucantars, or Almicanthers.—The Arabic term for *Parallels of Altitude*. These parallels were conceived to be drawn through every degree of the meridian. Obsolete.

Almanac.—The Arabic name for The Diary; its use, especially applied to the annual register of astronomical phenomena calculated beforehand, indicates, with numerous similar words, the channel through which our navigators have received much of the science on which their art depends.—See Nautical Almanac; Connaissance des Temps.

Alphard.—The Arabic name for the bright star a Hydra. —See Hydra.

Alpheratz. - The Arabic name for the star a Andromedæ, -- See Andromeda.

Altair.—The Ambie name for the bright star a Aquibs.—See Aquila.

In the Natural Almanae for 1846 however, the old custom has been reverted to of

Altitude of a Celestial Body.—(L. altitudo. "height").—
The angular distance of the body from the horizon. It is measured
"by the arc of a circle of azimuth (which is hence generally called a
circle of altitude") passing through the place of the body, intercepted
between the body and the horizon, or by the corresponding angle at
the centre of the sphere. The term altitude may be considered to
apply not only to elevation above the horizon, but also to depression
below it; and in that case it is reckoned from the horizon from 0 to
90°, to the zenith positive (+), and to the nadir negative (-). The
complement of the altitude is the zenith distance. Azimuth and
altitude are the horizon co-ordinates for describing points of the
celestial concave relatively to the position of an observer on the
earth's surface.—See Azimuth and Altitude.

Altitude of a Terrestrial Object above the Sea Horizon.—The angle

included between two lines drawn from the eye of the observer, the one to the horizon,

the other to the object. Thus in the example illustrated by the figure HSO is the altitude of the mountain above the sea horizon.

The observation of this angle furnishes the means of determining a ship's distance from the land. When the height of the summit or other point of high land is known one observation is sufficient. When the height is unknown the distance may be found while standing directly towards it, by means of two altitudes and the distance run in the interval between them. The methods of computation are given by Raper (Practice of Navigation p.p. 355—365, and published in a separate form by the Hydrographic Office.

Altitude-distinguished as Observed, Apparent and True. The Altitudes of heavenly bodies are observed, from the deck of a ship at sea, with the sextant for the different problems of Such an altitude is called the "Observed Altitude." There are certain instrumental and circumstantial sources of error by which this is affected; (a) The sextant (supposed otherwise to be in adjustment) may have an index error; (b) The eye of the observer being elevated above the surface of the sea, the horizon will appear to be depressed, and the consequent altitude in reality too great; and (c) One of the limbs of the body may be observed instead of its centre. When the corrections for these errors and method of observing are applied—the "index correction," "correction for dip," and "semi diameter" the observed is reduced to the "Apparent Attitude " But again, for the sake of comparison and computation. all observations must be transformed into what they would have been had the bodies been viewed through a uniform medium, and from one common centre -the centre of the earth. The altitude supposed to be so taken is called the "True Altitude." It may be deduced from the apparent altitude by applying (a') the "correction for refraction" and (b') "the correction for parallax," which two corrections, however, are sometimes given in tables combined under the name "Correction in Altitude." When a body is viewed through the atmosphere, refraction will cause the apparent to be greater than the true altitude; hence the correction for refraction is subtractive in finding the true from the apparent altitude. The position of the observer on the surface, capecially for comparatively near bodies, will cause the apparent to be less than thetrue altitude; hence the correction for parallax is additive in finding the true from the apparent altitude

Altitude, Meridian.—The altitude of a celestial body when on the meridian. In the case of a circumpolar star, whose whole diurnal circle is completed above the horizon, the body comes to the meridian twice, when its altitudes are spoken of respectively as "the Meridian Altitude below the Pole," and "the Meridian Altitude above the Pole;" the former is the lowest altitude the body has in its revolution, the latter the highest. The meridian altitude is easily observed at sea with a sextant, and furnishes the simplest and most satisfactory method of determining the latitude, the declination of the body being required in addition.—See Latitude, how determined.

Altitudes, Circummeridian, Exmeridian.—Terms applied to altitudes, other than meridian, taken for the determination of the latitude. Though employed sometimes in a general and sometimes in a specific sense, they are for the most part restricted to indicate such altitudes when taken "near the meridian" from which the meridian altitude can be deduced and the latitude thence obtained—the limits of nearness depending on the latitude, declination and the degree of precision with which the time is known. Some standard writers, such as RAPER, JEANS, DUBOIS and COFFIN, use the term "circummeridian"; while common usage has adopted the more modern and shorter term "ex-meridian," which is also stereotyed in familiar Tables which aid the solution of the Problem "Latitude by Reduction to the Meridian." Neither of the terms is found in Inman, who simply uses the unambiguous English phrases—"On the Meridian," "Off the Meridan," "Near the Meridian."

Altitudes, Combined.—Two altitudes, of the same ordifferent celestial bodies, taken for the solution of the same problem.

The term was suggested by RAPER in place of "Double Altitudes."

In a wider sense it may be usefully applied to describe generally all cases which are particularized under other and commonly accepted terms. It would thus include: "Merulian Altitudes above and below the Pole," "Double Altitudes," "Equal Altitudes."

Altitude a Double.—The term used in common parlance for a pair of combined altitudes taken to determine the latitude. These altitudes may be of the same body, taken at different times, or of different bodies, observed at either the same time, or at different times. See Latitude, how determined.

Altitudes, Equal.—The term generally used for a pair of combined altitudes taken to rate a chronometer.

The most accurate method generally available for finding the error of chronometer is by noting the time shewn when a celestial body has equal altitudes upon opposite sides of the meridian. One half of the interval clapsed added to the time shewn by chronometer at the carlier observation gives the time by chronometer corresponding to the meridian passage of the body, provided that no change has taken place in the declination and right ascension in the interval. And in the case of a star the ship Mean Time of passage is found by subtracting the R.A. Mean sun from the R.A. star increased by 24 hours if necessary, so that by comparing the time so found with that shewn by the chronometer the error is determined. By this method it will be observed that the errors of the instrument and the personal error of the observer are to a great extent eliminated, since, provided that the same altitude is observed on each occasion, the exact value of the altitude is unimportant. See Chronometer, Error of.

The principle of "Equal Altitudes" is sometimes applied in finding the longitude at sea. Its use however, must in the case of the sun be restricted to those parts of the world where the declination of the sun approaches in value the latitude of the place, that is, the regions about the equator. Under these circumstances the sun has a rapid motion in altitude until close upon noon, and may therefore be utilized for time observations. But if a considerable interval has to elapse between the observations the error in the Run of the ship, which has to be brought into account, would vitiate the accuracy of the result.

Altitudes, Equation of Equal.—When in finding the error of chronometer by Equal Altitudes the declination of the body (as in the case of the sun) has suffered any change in the interval between the observations, a correction has to be applied to the half-interval in order to obtain the time shewn by chronometer when the sun is on the meridian. This correction is called "the Equation of Equal Altitudes." It is generally given in the form of an expression of two terms, viz:—

 $E_s = \frac{1}{30}$  (tan d cot h - tan l cosec. h) dp''

where dp is the change in polar distance during the interval 2h.

The equation in this form is somewhat troublesome, chiefly on account of the difficulty in fixing the appropriate signs of the two terms. In the Nautical Magazine for February 1874, a method was proposed by Mr. W. H. Bolt for finding the two parts by inspection from certain Tables then published by Captain Trivett, but recently revised and republished in "Wrinkles of Navigation" under the name of "Lecky's Tables A and B."

A simpler form of the equation is:—  $\mathbf{E}^* = \mathcal{A}_{\mathbf{S}} \text{ (Sec } d, \text{ cot, PXZ) } dp^*$ 

where I'XZ is the angle at the body contained by the circles of altitude and declination, sometimes called "the angle of position." In this case we have for sign the simple rule. "When the body's distance from the elevated pole is increasing add, when decreasing subtract." If PXZ is greater than 90°, the rule is of course reversed, on account of the cotangent changing sign, but this can only occur in the tropics when (1) the latitude is less than the declination, and of the same name, and (2) when the observation is taken between the point of maximum azimuth and the meridian. For an observation taken at the maximum azimuth in such places, the equation vanishes; a fact which is worth remembering, since at this instant the sun is moving in altitude most rapidly, and is therefore best suited for observation."

In a valuable work on navigation by Mes. JANET TAYLOB, an expression in one term is given as follows --

E cot h cosec,  $\theta$  cosec  $p \sin (p - \theta) dp''$ .

where tan  $\theta = \cot l \cos h$ ; with the same rule for signs as that given above

Altitudes, Maximum and Minimum.—(L maximum, "greatest"; minimum, "least").—For a body of fixed declination, the maximum altitude is that at which it crosses the meridian above the pole, which is known as its Upper Culmination; its minimum altitude, in the case of bodies whose polar distance is less than the latitude of place, is the altitude at which it crosses the meridian

In a short tressise on "Types de Calculs 'contabilited by Captain Givou of the firmen Navy to the "Annales Hydrographiques" for 1895, published by the French Hydrographic Department, this form is adopted for the Equation.

below the pole, known as its Lower Culmination. When however the body is altering its position in the heavens, or the ship changing its place on the earth, the maximum and minimum altitudes are no longer the same as the altitudes upon the meridian, but take place earlier or later according to circumstances. Theoretically the change in [the right ascension of the body and in the longitude of the ship both have a certain minute effect, but practically it is sufficient to take into account the change in the declination of the body and in the latitude of the ship.

To find the time when a body is at its maximum altitude. Let k be the hour angle, p its polar distance, c the complement of the declination of the zenith (which corresponds with the co-latitude of the place on the terrestrial sphere); also let dp be the small change in the polar distance corresponding to the small change dh in the hour angle. Then the interval that should be applied to the time of the meridian passage to obtain the time of maximum altitude is given by the formula

$$h = \frac{1}{15 \sin 1''} \frac{\sin (p-c)}{\sin p \sin c} \frac{dp}{dh}$$

Formerly the difference between the maximum altitude and the meridian altitude was only noticeable in the case of the moon, the declination of the other heavenly bodies changing relatively so slowly; but of late years the largely increased speed of modern steamships has rendered it necessary to pay attention to the distinction in other cases.

The investigation of the above formula will be found in MERRIFIELD'S Treatise on Nautical Astronomy. A small Table for acilitating the reduction of the maximum and minimum altitude

The Ex Meridian treated as a Problem in Dynamics," the mg intended for use in combination with BRENT, WALTER MANS' Ex-Meridian Tables.

ndes, Simultaneous. - Combined altitudes of different sten at the same time.

tides, Circles of.—Great circles of the celestral concave talar to the horizon, and so called because "altitudes" are ton them. They all pass through the poles of the horizon, of superior pole, or zenith, is the "vertex" of the visible heavens, they are also called "Vertical Circles," or simply "Verticals." system of horizon co-ordinates they are termed "Circles of as marking out all points that have the same "azimuth." Fordinates for the Surface of a Sphere.

nde, Circles or Parallels of Equal. Circles on the arface, from every point of each of which a given heavenly observed to have the same altitude at any given time. The equal altitude is a great circle of the sphere when the body horizon, or its altitude 0; the circle is reduced to a point body is in the zenith, or its altitude 90° and between limits the parallels are small circles whose radii correspond aptements of the altitudes. A small are of a circle of equal when projected on a Mercator's chart, will be approximately line, especially if the altitude of the body be low. Such a lad "A Line of Equal Altitude." The determination of one, such lines intersecting each other, forms the basis of what is summer a Method " of finding a ship's position at sea.—See Parallels of.

Altitude Parallels of.—Small circles of the celestial concave whose planes are parallel to the horizon. They mark all the points of the heavens which have the same altitude. The Arabic term for this system was "Almucantars." Compare "Parallels of Declination," "Parallels of Latitude."—See Co-ordinates for the surface of a Sphere.

Altitude, Correction in.—The total correction to be applied to the apparent altitude to deduce the true altitude. In the case of the stars, it is due solely to refraction, but for appreciably near bodies to the combined effects of refraction and parallax. When the effect of refraction is greater than that of parallax the correction is subtractive, when the effect of parallax is greater, as in the case of the Moon, it is additive. Separate tables of the "Correction in Altitude" are given in works on navigation for the stars, the sun, and the moon.

Altitude, Reduction of, to another Place of Observation.—See Run, Correction for.

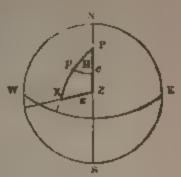

Altitude, Motion in.—An instrument is said to move "in altitude" when it is turned on a horizontal axis; in contradistinction, it is said to move "in azimuth" when it is turned on a vertical axis. An azimuth and altitude instrument admits of both motions.

Altitude, how found by Calculation.—Given the latitude of the place (l), the declination of the celestial body (d), and the hour angle (H), to find the altitude of the body (a). Project on the horizon. Z is the zenith, P the elevated pole, and X the body. Let  $c=90^{\circ}-l$ ,  $p=90^{\circ}-d$ ,  $z,=90^{\circ}-a$ . Then in the triangle PZX, cos  $z=\cos c$ .  $\cos c$ .  $\cos p$  +  $\sin c$ .  $\sin p$  cos H.

This, reduced for logarithmic computation, gives the following three methods of solving the problem, according to the tables in use.—

(L) Sin 
$$\frac{H}{2} \sqrt{\sin c \sin p}$$
  
Sin  $\frac{c^2}{2} = \frac{\sin \theta}{\sin \theta}$   
where  $\theta$  is obtained from the formula.

Sin 
$$\frac{H}{2}$$
  $\sqrt{\sin c \cdot \sin p}$ 
Tan  $\theta = \sin \frac{1}{2} (c \sim p)$ 

(II) Vers  $z = \text{vers } (c \sim p) + \text{vers } \theta$ where vers  $\theta$  is obtained from the formula

Vers 
$$\theta = 2 \sin c$$
,  $\sin p$ ,  $\sin^2 \frac{H}{2}$ 

(III.) Vers  $z = \text{vers}(c \sim p) + \text{vers} \theta$ 

Where  $\theta$  is obtained from the formula

Hav  $\theta = \sin c \sin p$  hav H

or L hav  $\theta = L \sin c + L \sin p + L \text{ hav } H - 20$ .

This is the simplest form, but requires the possession of a Table of logarithmic Haversines.

Another form of the expression for finding  $\theta$  is:—
Log tab very  $\theta = L$  sin c + L sin p + L hav H = 30 + 6.301030,
but the use of this is now almost obsolete.

An application of this problem may be seen in one of the method of working a lunar

A.M.—The initials of "Ante Meridiem," "Before Noon," opposed to P.M., "Post Meridiem," "After Noon."

Amplitude of a Heavenly Body (L. amplitudo, "extent").

—The distance from the "east point" at which the body rises, or the distance from the "west point" at which it sets; these distances being arcs of the horizon measured northward or southward. The amplitude is sometimes called the Rising or Setting Azimuth, and is then reckoned from the north or south point, according as the south or north pole is elevated. It has been objected to the continued use of this term. Amplitude, that we generally in fact observe the bearing of the body with the azimuth compass from the N. or S., and then convert this to its bearing from E. or W. But it is, on the other hand, advantageous to retain a term so expressive and marking a particular case. It is as natural to speak of the amplitude—referring the body to the E. or W. point—as it is to speak of an object as two or three points abaft or before the beam.

Amplitude, True.—The bearing of a celestial body at rising or setting (i.e., when its centre is on the rational horizon) from the true east or west point; found by calculation from the latitude of the place and the declination of the body, or taken by inspection from a table of which these quantities are the arguments. It is in general simply called "the Amplitude," but it is sometimes qualified as the True Amplitude, to distinguish it from the Compass and Magnetic Amplitude.

Amplitude, Compass.—The bearing of a celestial body at its rising or setting from the compass east or west point; found by direct observation with an instrument carrying a magnetic needle, corrections being then made for dip, refraction, and parallax. The difference between the true and compass amplitude gives the correction (variation and deviation combined) of the compass, or as it is usually termed the "compass error."

Amplitude, Magnetic.—A term sometimes used for the bearing of a celestial body at rising or setting from the compass east or west points; found by direct observation with an instrument on shore when not affected by deviation. It is distinguished from the True Amplitude, or Amplitude properly so called, and from the Compass Amplitude.

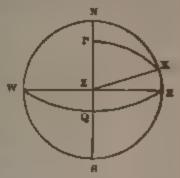

Amplitude, Magnetic-distinguished as Observed and Corrected .- The " Observed " Magnetic Amplitude of a celestial body is its bearing from the compass east or west point when it appears in the sea horizon of an observer standing on the deck of the ship. The "Corrected Magnetic Amplitude is the bearing of the tody from the compass east or west point when on the rational horizon, as it would appear to a spectator at the centre of a sphere through a uniform medium. The diurnal circles of the celestial bodies being, except at the equator, inclined to the horizon, and more and more so the higher the lititude, any cause which affects the time of rising will affect the apparent amplitude, in a degree becoming greater as the latitude mereases. These causes are the following : (1) The elevation of the observer depresses the sea-horizon, while it does not affect the place of the celestral body-hence, by reason of the dip, the body appears to rise before it is truly on the sensible horizon: (2) The great refraction at the horizon causes the body to appear to rise considerably before it comes to the sensible horizon; (3) When a body is in the sensible horizon to an eye at the centre of the aphere it has stready passed the rational horizon. This, being the effect of puruliar, is only of importance in the case of the moon. These corrections will be found in the tables given in the ordinary treatises on navigation.

Amplitude, Bearing and Time.—By the "Bearing Amplitude of the Sun" is meant the arc of the horizon intercepted between the east point and the point where the sun rises, or between the west point and the point where it sets. By the "Time Amplitude of the Sun" is meant the time he rises before or after 6 A.M., or sets after or before 6 P.M. When the latitude and declination are of like names, the sun rises so much before 6 A.M., and sets so much after 6 P.M.; when they are of different names, the sun rises so much after 6 A.M., and sets so much before 6 P.M.

Amplitude, Observation of.—The usual instructions, for taking amplitudes, are laid down with the view that the body shall be observed at the moment when its centre is really in the rational horizon. Thus the bearing of the sun is directed to be taken when its lower limb appears half-way between the horizon and its centre; the bearing of a star is to be taken at an altitude of 34': the amplitude of the moon cannot be thus directly observed with accuracy, especially in high latitudes, by reason of her great depression by parallax, but may be found approximately by observing her bearing when her upper limb is in the horizon. In all cases, however, the better plan is to obtain by observation the bearing when the centre of the body appears on the horizon, and apply the necessary corrections (for dip, refraction, and parallax) taken from a table. For the sun, when rising, observe the bearing of the upper limb as it appears on the horizon, and continue to take bearings of the vertex until the lower limb appears. Read off each bearing. At sunset, when the lower limb touches the horizon, proceed in like manner until the upper limb disappears. The mean of the readings, reckoning from the east or west point, is the observed amplitude of the centre; when practicable the moon may be observed in the same way. In the case of the sun and stars, a table (with latitude and declination for arguments) gives the necessary correction for refraction, to which the requisite dip is added. The same table applied in the contrary way gives the correction for the moon, which

in the excess of the effect of parallax over the combined effects of refraction and dip. The amplitude of a star should be observed at extens, to admit of the body being easily becomes

Amplitude, how found by Calculation. The figure is a projection on the horizon. No is the meridian, EQW the

equator, Z the zenth. P the elevated pole, and X the body in the horizon. Then PZX is a quadrantal triangle  $(ZX=90^{\circ})$ , in which, having given PZ the colatitude  $(c=90^{\circ}-l)$ , PX the polar distance  $(\mu=90^{\circ}\pm d)$ , we can determine the angle PZX, which is the complement of EZX the amplitude (a).

Con PX = sin PZ con PZX

 $\sin a = \sin d \sec l$ 

... Lisin a = L ain d + L, sec l = 10.

The amplitude can be taken out approximately by inspection from a table constructed for the purpose, and given in most works on cavigation, the argumenta being the declination and latitude. The principal application of this problem is in finding the error (variation and deviation combined) of the compass. The method should be avoided in high latitudes, when the sun skims along the horizon, and an error of several degrees may easily result. See Compass Corrections

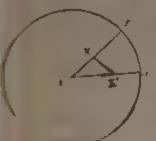

Andromeda.—A constellation between Pegasus and Perseus, and to the south of Cassiopeia and Cepheus. These groups were named by the Greeks after persons in their mythology. Andromeda was the daughter of Cepheus and Cassiopeia, who, being bound to a rock, exposed to a sea-monster, was delivered by Perseus. The four stars of Pegasus, forming a remarkable square, can always be recognized after being once pointed out; one of these stars (the most northerly) is common to Pegasus and Andromeda, and called δ Pegasior a Andromeda. The three principal stars of Andromeda form a line joining Pegasus to Perseus, a Andromeda (called Alpheratz), Mag. 2.1: 1896, R. A. 0h. 3m., Dec. + 28°31′. β Andromeda (called Mirach), Mag. 2.2; R. A. 1h. 4m., Dec. + 35° 4′. γ Andromeda (called Alamak), Mag. 2.1; R. A. 1h. 58m., Dec. + 41° 50′.

Aneroid Barometer (Gk. a "without;" rnpds, "fluid").—A barometer into the construction of which mercury or other fluid does not enter. Other derivations of the word have been given; thus it is said that M. Vidi, the inventor, intended to call the instrument an Aneroid Baroscope, as by it the pressure of the atmosphere is "perceived," in a manner similar to that by which changes in elasticity of the atmosphere affect the body of a man (drhp, "a man")—See Barometer.

Angle of Position.—In the spherical triangle PXZ, in which PZ is the colatitude, PX the polar distance, and ZX the zenith distance the angle subtended at the body X by the colatitude PZ is sometimes called the "Angle of position."

"Angle of the Vertical."—See Latitude, Reduction of.

Angular Distance.—The angular distance of two remote bodies is their apparent distance, as measured by the angle they

subtend at the eye of the observer. This is an important element in celo-navigation, for all beavenly bodies appear on the surface of the celestial concave, and it is by their observed angular distances that their relative positions furnish data in the problems of navigation. Thus, let E be the centre of the earth, X and X'

two heavenly bodies at an absolute distance from each other XX'. They appear, as seen from E, to be projected at x and x on the celestial concave. The angle XEX', or the arc xx', is called their angular distance.

Antarctic Circle (Gk. derl, "opposite to "decres," The Bear ') The "South Polar Circle," or parallel of latitude about 66° 33' S. It encircles the south pole at the same distance from it as the tropical circles are from the equator (about 23° 27'), and it includes within it the south frigid zone, which it separates from the south temperate zone. It is called the "Antarctic" circle, as being on the opposite (deri) side of the globe to the "Arctic" circle—See Arctic Circle.

Antares. -The Arabic name for the bright star a Scorpii, -See Scorpius.

Ante Meridiem (L. "Before Noon;" abbreviated A.M.) The designation of the first twelve hours of the civil or nautical day those, before the sun has arrived at the meridian. The other twelve are distinguished as the hours "Post Meridiem" (Abbreviated P.M.)

Aphelion (Gk. dwd "away from;" flaces, "the sun").—Every planet revolves in an ellipse round the sun, situated in one of the foci. That point in its orbit farthest from the sun is called the Aphelion, that nearest to the sun the Perihelion.

Apogee (Gk.  $d\pi\delta$ , "away from;"  $\gamma\hat{\eta}$ , "the earth").—The moon revolves in an ellipse round the earth, situated in one of the foci. That point of her orbit farthest from the earth is called the *Apogee*, that nearest to the earth the *Perigee*.

Apparent (L. apparère, "to appear").—An adjective indicating that which appears to the senses.

- l, "Apparent" is sometimes equivalent to true or real, when contrasted with fictitious or imaginary. Thus the "apparent sun" is the true sun which we see, as opposed to the imaginary "mean sun;" apparent time" is measured by the hour-angle of the same sensible body and is opposed to "mean time," which is defined by the movement of the fictitious mean sun; "apparent noon" is the instant when the true sun is on the meridian, and is distinguished from the "mean noon," which is marked by the transit of the mean sun.
- 2. "Apparent" is sometimes used as a qualification, distinguishing on the one hand from observed, and on the other from true. It is in this sense applied to elements corrected for instrumental and circumstantial sources of error, but not yet reduced to the common standard for comparison and computation. We thus have the "apparent altitude" of a heavenly body, and the "apparent distance" of two heavenly bodies, distinguished on the one hand from the "observed" and on the other from the "true" altitude and distance. So also there is the "apparent place" of a heavenly body in the celestial concave, and the "true place."

3. "Apparent" is sometimes opposed to proper, to distinguish the phenomenal diurnal motion of the heavenly bodies resulting from the earth's rotation on her axis, from that which is due to the annual revolution of the earth in her orbit, and to the motion of each body in its orbit.—See under each term qualified.

"Apparent Time of Change Tide."—The date of "change tide," which is expressed in apparent time. The simple term "change tide" is commonly used when speaking of this date.—See under Tide.

Approximations; Approximate Method.— Approximations are approaches nearer and nearer to the quantity sought. An approximate method of solving many problems in navigation is one in which rough values of elements are used and general conclusions drawn. The results of an approximate method are often most valuable. It is frequently the only one that can be used in cases of haste; it may be conveniently applied when precision is not necessary; and it furnishes an easy check against mistakes which may occur in the more elaborate work of the rigorous method.

Aquarius, the Constellation of, (L. Aquarius, "The Water Bearer: "Gk. υδροχοευς, "The Water-Pourer").—The eleventh constellation of the ancient zodiac, indicating a wet season of the year. The number of visible stars in this group is very great, but they are all small. a Aquarii Mag 3.2; 1896, R.A. 224, Dec. . U. 50.

Aquaritis, the Sign of. That portion of the celiptic which extends from 300° to 330° longitude. Owing to the precession of the equipoxes, the sign does not coincide with the constitution of this

name, the sign at present occupying part of the constellations Capricornus and Aquarius. The sun is in Aquarius from about January 20th to about February 20th. Symbol .....

Aquila (L. "The Eagle").—A constellation containing an important star a Aquilæ formerly called Altair. It can readily be found by drawing a line from the two bright stars of Draco to Lyra, and continuing it to twice the distance. This is one of the stars of which the "lunar distances" are calculated and tabulated in the Nautical Almanac, and which is therefore useful in finding the longitude. Mag. 1.0. 1896, R.A. 19h. 46m, Dec. +8° 36'.

Arc (L. arcus "a bow").—A portion of a curve, as of the circumference of a circle or an ellipse.

Arc Proper.—The arc of an instrument for taking angles, is graduated from zero through the range which the instrument is adapted to observe. This graduated arc is called "the arc proper."

Arc of Excess.—In instruments for taking angles the zero of the arc is not coincident with its extremity, and the portion of the arc so excluded is graduated in an opposite direction to the arc proper; this portion is called the "arc of excess." It is necessary for finding the index correction. In observing small angles, if a pair of observations be taken, one directly and the other reversely, the mean of the readings, one "on" and the other "off" the arc, will give the angle free of index error. This is important in nautical surveying.

Arctic (Gk. apkros, arklos, "a bear").—A term synonymous with "northern," derived from the constellations of the Great Bear and the Little Bear, which are the most conspicuous of those adjacent to the north pole of the heavens.

ARGO.

Arctic Circle (Gk. Aperos, "a bear") The "North Polar Circle." or parallel of latitude of about 66° 33′ N. It encircles the north pole at the same distance from it as the tropical circles are from the equator (about 23° 27'), and it includes within it the north frigil zone, which it separates from the north temperate zone. The term was applied originally to the celestial parallel of declination of about 60° 32′ N., within which is situated the important constellation of the Great Bear.

Arcturus. (Aparos. "a bear;" objos, "a warder," "The Bear Keeper") -A bright star in the constellation Bootes, marked in modern catalogues a Bootis. This constellation Bootes, which used also to be called Arctophylax (Aparot, "a bear;" φύλαξ, "a watcher") is situated behind the tail of the Great Bear. Arcturus can easily be found by continuing the curve formed by the three stars of the Bear's tail, to almost twice its length. It is one of the stars observed to have a proper motion. Mag. 0.0. 1896, R.A. 14h 11m, Dec. + 19°43'.

Argo. (Argo, Argos, the ship of Jason, the gentleman adventurer and navigator of mythical times).—A very extensive constellation of the southern hemisphere, of which the several parts are named, Carma, "the Keel; "Puppis, "the Poop" Malus, "the Mast;" and Vela, "the Sails." It is to the south-east of Canis Major. The star a Argos (called Canopus) is one of the brightest in the heavens. Procyon, Sirius, and Canopus are in a line, running along the south-east of Orion, by which indication Canopus may be found; or a line from Rigol through a Columba, and produced about half the same distance, will terminate near Canopus; or again, it may be identified by the Sword of Orion, which points directly towards it.

Mag 0 4. 1896, R.A. 6h. 22m Dec. - 52° 38', n Aryth is a variable star changing from magnitude 1 to 7.5 in the period of 70 years. 1896. R.A. 10h 41m. Dec. - 59° 8'.

Argument (L. argumentum, "reason"). -In astronomical tables the argument is that quantity upon which the tabulated one depends, and with which, therefore, the table is "entered" Thus, in a table of correction for refraction, the altitude is the argument. When the element tabulated depends upon two given ones, then there are two arguments with which to enter the table -one at the side, the other at the top. Thus, for the correction for the moon's altitude, the arguments of the principal table are the apparent altitude and the minutes of the moon's horizontal parallax.

Aries, the Constellation of (L. Aries "The Ram").—The first constellation of the ancient zodiac, marking the period for the commemoration of the mythical Golden Fleece connected with the ship Argo. The only two stars in it, of any note, are a and \$\beta\$ near together in the horns, a being the more northerly. a Arietis (called Hamel) is one of the stars of which the "lunar distances" are calculated and tabulated in the Nautical Almanac, and therefore important for finding the longitude. Mag. 2; 1896, R.A. 2h. 1m, Dec. + 22° 58'. \$\beta\$ Arietis, Mag. 2.8; 1896, R.A. 1h 49m. Dec. + 20° 18'. The group can easily be found: either, by continuing the line from Procyon through Aldebaran to about the same distance beyond it, when it will pass a little to the south of the two stars, reaching a first; or again, the line joining the Pleiades and Algenib is bisected by \$\beta\$ Arietis.

Aries, the Sign of. The division of the scliptic including the first 30° of longitude, reckoning from the vernal equinoctial point

or first point of Aries. This origin, owing to the precession of the equinoxes, is at present in the constellation Pieces. The sun is in Aries from March 21st to April 20th. Symbol 7.

Aries, First point of. - The "Vermal Equinoctial Point," one of the points where the ecliptic crosses the equinoctial, so called as being the commencement of the sign Aries. -- See Equinoctial Points.

Arithmetical Complement. The complement of, a quantity is what must be added to it to make it equal to some fixed quantity. In the case of numbers, the fixed quantity is generally 10, 100, or the power of 10 next higher than the number in question; thus the ar. co. of 756 is 1000 - 756 - 244. The arithmetical complement of a logarithm is the difference between the logarithm and 10; thus the ar. co. of log. 4 is 10 - log. 4 - 10 | 002060 = 9:397940; the ar. co. of log. \( \frac{1}{2}\) is 10 - 2:602060 = 11:397940. In practice, the arithmetical complement of a logarithm (which is often wanted) is most easily found by taking each digit from 9 except the last significant one, which is to be taken from 10.—See Complement.

Artificial Horizon.—A reflector whose surface is perfectly horizontal, used for observing altitude.—See Horizon, Artificial.

Artificial Projections.—Delineations of a surface on a plane traced according to fixed laws, but not being perspective representations. Example, Mercator's projection of the sphere. Distinguished from Natural Projections.—See Projections.

Astrolabe. (lik dorne, "a star;" happaner, "to take").

A very uncient instrument for taking observations of the stars, the
form of which has varied in different ages. Its principle rested upon

the fact that the circles of the celestial concave and those of a small globe may be considered concentric, having the observer's eye at their common centre. The Astrolabe used by navigators was simple an annular disc graduated into 360°, and having a moveable diameter carrying vanes; the instrument being suspended by a ring at the point corresponding to the zenith. This, as Sir Jonas Moore says is the first and most natural instrument of all others, and, before the invention of the sextant, it was "no contemptible instrument,"

"Astronomical Bearings."—The method of finding the true bearing of a terrestrial object by referring it to some celestic body. The difference of bearing of the two being obtained, and the azimuth of the celestial body being known, the true bearing or azimuth of the terrestrial object can be determined —See Azimuth (True of a Terrestial Object, how found.

Astronomical cross Bearings.—A name given to the Summer method of fixing the position of a ship by two lines obtained by astronomical observations.

Astronomical Clock.—A clock of superior construction, an specially adapted for astronomical observation — See Clock.

Astronomical Day. -The day used by astronomers, are to which their observations are referred; it is distinguished from the civil day, which regulates the ordinary business of life.—See und. Day.

Astronomy (Gr. dorne, "a star," any celestial luminary roper, "a law") —The science which treats of the great bodie which make up the visible universe. It is generally divided into (Plane Astronomy, which deals with the magnitudes, distance arrangements, and motions of the heavenly bodies, as facts which

are matters of observation; (2) Physical Astronomy, which investigates phenomena on the principles of mechanics, and refers them to general laws. That portion of Plane Astronomy which is applied to the purposes of navigation is called Nautical Astronomy. When this term is used to described a branch of navigation, it is not a suitable one.—See Gelo-navigation

Atmosphere (Gk. aruds, "vapour;" σφαίρα, "a sphere"). -The mass of air enveloping the earth, and constituting a coating of equable or nearly equable thickness. This acrial ocean, of which the surface of the sea and land forms the bed, diminishes in density very rapidly, till, within a moderate distance from the earth, all sensible trace of its existence disappears. One-thirtieth of its whole mass is included within 1000 feet, and one-half of the whole within 18.000 feet, from the surface of the earth; and there is, practically speaking, no air at a distance above the earth's surface of the one-hundredth part of its diameter. There is probably an absolute and definite limit to the atmosphere. The atmosphere is always kept in a state of circulation owing to the excess of heat in its equatorial region over that at the poles, and clouds float in its lower strata. This is the special province of the meteorologist, whose observations, investigations, and inventions are of such importance to the seamen. The atmosphere is also a subject of important consideration for the narmer, by reason of its effect in modifying astronomical phenomena. -See Refraction; Twilight.

Atmospheric Pressure.—The atmosphere presses equally in every direction; its effects therefore are not sensible upon bedies wholly immersed in it. But if the air be withdrawn from one side of body, the pressure on the rest of the surface is at once make

evident. In nature, we have illustrations of the working of this truth in the force which keeps the limpet on the rock and enables the fly to walk on the ceiling. Experiments have established the principle and given the actual amount of the pressure, which is found to be about 15lb. on the square inch. Torricelli, in 1643, ascertained the height of the column of mercury that could be kept in equilibrium by the pressure of the atmosphere, thus laying the foundation of the construction of the mercurial barometer. Pascal, by an experiment in 1648 upon the Puy de Dôme, demonstrated that the pressure decreases with the height above the surface of the earth. A partially inflated bladder was the simple instrument used, but the idea has been elaborated in the aneroid barometer.—See Barometer.

Augmentation of the Moon's Horizontal Semi-diameter.—See Moon.

Auriga (L. "The Charioteer").—A constellation containing five principal stars forming a great irregular pentagon. It is most easily found in connexion with Gemini, its two brightest stars (α and β) forming a pair similar to Castor and Pollux, and lying alongside of Taurus as Gemini does near Orion; also, as Castor is the upper star of the Twins, so Capella is the upper star of Auriga. Capella (α Aurigæ) is a very bright star, and can also be distinguished by having close to it a long isosceles triangle formed by three small stars. Mag. 1; 1896, R.A. 5h 9m, Dec. +45° 54′.

Autumnal Equinox (L. autumnalis, "pertaining to the autumn").—Relatively to the northern hemisphere, the Autumnal Equinox is that period when the sun crosses from the north to the south of the equinoctial; about September 23rd.—See Equinoxes.

Autumnal Equinoctial Point. -Relatively to the northern bemisphere, the Autumnal Equinoctial Point is the point of interwhen of the coliptic with the equinoctial, where the sun crosses from the north to the south of the equinoctial. It is more generally called 'The First Point of Libra." - See Equinoctial Points.

"Auxiliary Angle A."—A subsidiary angle, the use of which facilitates the process of "clearing the distance" in finding the longitude by lunar. Let d be the true distance, d' the apparent distance; the true zenith distance of the moon, v that of the other ody; m' the apparent altitude of the moon, v that of the other body.

Then it may be deduced from the equation:

tiest-

$$\cos d - \cos (z - v) = \begin{cases} \cos d + \cos (m' + s') \end{cases} \frac{\sin z \sin v}{\cos m' \cos s'}$$

Assume-

then-

2 cos A sin a sin a sec m' sec s'

Leve A = Lain z + L and v + L sec m' + L sec a' - 30 301030

from which expression the values of A may be computed and formed ato a table. In Inman, one table (Table a) gives "The Correction of the Moon's apparent Altitude and the Auxiliary Angle A," the arguments of which are the apparent altitude of the moon and the alientes of her horizontal parallax; additions being made dependent the seconds of the horizontal parallax and the apparent altitude

of the other body observed. By the use of this table, together with one of versines, d may be found with much less labour than by the usual rules of spherical trigonometry.

Students frequently inquire how Inman's Two Tables (the larger one with argument "App. Alt. (", the smaller one with argument "App. Alt. © or © ") are obtained from the expression

$$2 \cos A = \frac{\sin z \sin v}{\cos m' \cos s'}.$$

As we have not seen the explanation in print the following investigation may be appreciated. The first of these is due to the late Rev. F. Davies, M.A., formerly a Naval Instructor in the Royal Navy.

By formula 
$$2 \cos A = \frac{\sin z \sin v}{\cos m' \cos s'}$$
.

Let  $A = A' + \theta$ , where A' is determined by making  $\frac{\sin v}{\cos s'} = 1$ .

Then 
$$2\cos A' = \frac{\sin z}{\cos m'}$$
 - (i)

To determine  $\theta$ , if p', q' are respectively the corrections in altitude for the moon and the other body, so that  $m'+p'=90^{\circ}-z$ ,  $s'-q'=90^{\circ}-v$ .

$$2\cos{(A'+\theta)} = \frac{\cos{(m'+p')}}{\cos{m'}} - \frac{\cos{(s'-q')}}{\cos{s'}} - \qquad (ii)$$

Dividing (ii) by (i) 
$$\frac{\cos (A' + \theta)}{\cos A'} = \frac{\cos (s' - q')}{\cos s'}$$

 $\cos \theta - \tan A' \sin \theta = \cos q' + \tan s' \sin q'$ 

Where  $\theta$  and p' being small angles, we may make  $\sin \theta = \theta$ ,  $\sin q' = q'$ , and  $\cos \theta = 1$ ,  $\cos q' = 1$ .  $\theta$  tan A' = -q' tan  $\theta'$ ,

Or if we give A' the approximate value of 60°,  $\theta = \frac{q' \tan s'}{\sqrt{3}}$ 

Since  $\theta$  is always subtractive, in order to make both corrections additive, 34" is deducted in the large table, and restored by addition in the small table.

2. By the use of logarithms.

$$\log \cos A \quad \left\{ \log \cos \left( m' + p' \right) + \log \sec m' - \log 2 \right\} + \left\{ \log \cos \left( s' - q' \right) + \log \sec s' \right\}.$$

The main part of A is determined by the first bracket. Call this A' as before. The second bracket changes the value of A' by less than one minute.

Let P be the value of  $\begin{cases} \log \cos (s'-q') + \log \sec s' \end{cases}$  for a given altitude. Also let Q be the change of  $\log \cos A$  (supposed = 60°) for one minute.

By the principle of proportional parts  $\theta = -\frac{P}{Q}$  60"; and at 60°, Q = 000219.

To make the above clear, an example is desirable. Take

App. Alt. 4 
$$m' = 73^{\circ} 42' 12''$$
 App. Alt.  $\odot = n' = 30^{\circ} 1' 59''$ 
 $p' = 15 42$  App. Alt.  $\odot = n' = 30^{\circ} 1' 59''$ 
 $p' = 15 42$   $q' = 1 33$ 

H.P. =  $56 55$ 

1st Method.  $\cos A' = \frac{1}{2} \frac{\sin z}{\cos m'} = \frac{1}{2} \frac{\cos(m' + p')}{\cos m'}$ ,  $\theta = -\frac{q' \tan s'}{\sqrt{3}}$ 

L.  $\cos 73^{\circ} 57' 54'' = 9.441262$   $\log 93'' = 1.968483$ 
L.  $\sec 73 42 12 = 10.551895$  L.  $\tan 30^{\circ} 1' 59'' = 9.762018$ 
 $9.993157$  Sum =  $1.730501$ 
 $\log 2 = 301030$   $\log \sqrt{3} = .238560$ 
L.  $\cos A' = 9.692127$   $\log \theta = 1.491941$ 

$$A' = 60^{\circ} 30' 57'' \qquad 60^{\circ} 30' 57'' \qquad \theta = -31''$$

$$\theta = 31 - 34 - 34 - 34 - 31 = 3''$$

$$Tab. A' = 60 30 26$$

$$Tab. A' = 60 30 26$$

2nd Method. A' is found as before.

For  $\theta$ . At altitude 30° change of logarithms for 93", the value of q, is 000113=P.

Then  $\theta = -\frac{P}{Q} 60'' = -\frac{113}{219} 60'' = -31''$ , as by first Method.

See Lunar Distance, Clearing the.

Axis (L. axis, "the axle-tree").—A straight line of reference with regard to position and phenomena. Thus we have for defining the position of points, co-ordinate axes, and we have the magnetic axis of a bar of steel. The two principal applications of the term are with reference to the two cases respectively of symmetry and In a plane figure the axes are straight lines, on both sides of each of which the figure is symmetrical; each dividing the figure into two parts in such a manner that all perpendiculars to it, terminated by the boundary of the figure, are bisected in the axis. Upon such a line the figure has no tendency to turn in either direction, but if made to rotate, it will generate a solid, also symmetrical, about the the same axis, for in such a solid all perpendiculars to the axis terminated by the boundary of the solid are bisected in the axis. Examples:—Every diameter of a circle is an axis, and if the circle be made to rotate about any of one of them, a sphere will be generated having that diameter as axis. An ellipse has only two axes, the longest and shortest of its diameters, which are called the major or minor axes; if made to rotate about the major axis, a prolate spheroid wil be generated; if about the minor

with it the idea of rotation, and in this view the following definition is comprehensive. The axis of a plane figure is a straight line which divides it into two such halves that if each were to rotate about this line they would both generate the same solid, and this solid has the same line for its axis.

Axis of the Earth.—That diameter upon which the earth rotates diurnally from west to east. In consequence of this rotation the earth has assumed its present form—an oblate spheroid, being compressed at the extremities of the axis (the poles), and bulging in the regions most remote from them (the equatorial). With reference to its extremities, the axis is called the "Polar Diameter."

Axis of the Heavens That diameter about which the celestial concave appears to revolve diarnally from east to west. It passes through the observer's eye, and is parallel to the axis of the earth, with which it is generally considered coincident.

Azimuth (Arabic). -The following articles are arranged in a materal, unstead of an alphabetical, order.

Azimuth of a Celestial Body.—The arc of the horizon intercepted between the north or south point and the circle of azimuth passing through the place of the body. Or it may be defined to be: — The angle at the zenith contained between the vertical circle passing through the elevated pole (the meridian), and the vertical circle passing through the object. Azimuth is usually reckoned from the north or south point eastward and westward from 0 to 180°. Sametimes the intersection of the horizon with that part of the negation which is on the polar side of the zenith, is taken as the zero point; but Sir John F. W. Herschel recommends that, to avoid

confusion, and to preserve consistency of interpretation when algebraic symbols are used (a point of essential importance), azimuth should be always reckoned from the point of the horizon most remote from the elevated pole westward (so as to agree in general direction with the apparent diurnal motions of the stars), and its reckoning be carried from 0 to 360° if always reckoned positive, considering the eastward reckoning as negative. Azimuth and altitude are the horizon co-ordinates for describing the points of the celestral concave relatively to the position of an observer on the earth's surface. When a body is in the horizon, the element used to define its position is the "amplitude," which is the complement of the azimuth in this case. Instead of this special term, the expression "Rising and Setting Azimuth" has been suggested.

Azimuth, Circles of.—Great circles of the celestial concave passing through the poles of the horizon, and so called because they severally mark out all points which have the same azimuth. They are also often called "Tertical Circles," or simply "Terticals," as passing through the "vertex" of the visible heavens; or "Circles of Albitude," after the element that is measured, not by them, but upon them—the "altitude." Compare "Circles of Right Ascepsion," "Circles of Longitude."—See Co-ordinates for the Surface of a Sphere.

Azimuth of a Terrestial Object.—The azimuth of an object is the angle between the meridian and the vertical circle passing through the object. On a horizontal plane, this angle is that between the "meridian line" and the line from the eye to the point of the compass on which the object is seen. The word Aumath is, therefore, used not only of celestial objects, but of terrestrial ones also, through the more usual term in this case is "Bearing."

Azimuth, True.—The bearing of an object from the true north or south point; it is the azimuth found by calculation from the observed altitude or hour angle of the body. It is in general simply called "The Azimuth," but it is qualified as the True Azimuth to distinguish it from the Compass and Magnetic Azimuth.

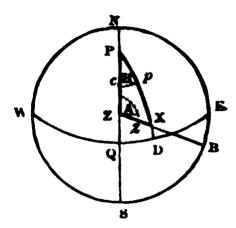

Azimuth, Compass.—The hearing of the object from the compass north or south point; found by direct observation with an instrument carrying a magnetic usedle. The difference between the true and compass azimuth gives the correction (variation and deviation combined) of the compass.

Azimuth, Magnetic. A term sometimes used for the bearing of an object from the compass north or south point, found by direct observation with an instrument fitted with a magnetic needle, not affected by deviation. It is distinguished from the True Azimuth, or Azimuth properly so called, and from the Compass Azimuth. Since refraction and parallax take place vertically, they do not affect the observed magnetic azimuth of a body. In using the azimuth compass, the bearing of a celestial body is most conveniently observed when its altitude is low; it is also then less affected by any error in the verticality of the sight-vanes.

Azimuth Compass.—A compass specially adapted for observing bearings.

Azimuth Mirror. A mirror being the internal surface of one of the faces of a prism attached to azimuth compasses, either for reading off by reflection the graduation on the card while the object is viewed directly, or for viewing the object by reflection while the graduation on the card is read directly. Azimuth how found by Calculation.—The figure is a projection on the horizon. NS is the meridian, EQW the equator,

Z the Zenith, P the elevated pole, and X the body. Draw the circle of declination PXD, and the circle of altitude ZXB. SZB is the azimuth, and it can be found by determining the angle PZB, which is its supplement. In the triangle PZX, PX is the polar distance  $(p=90^{\circ}\pm d)$ , PZ is the co-latitude  $c=90^{\circ}-l$ , ZX is the zenith distance  $(z=90^{\circ}-a)$ , ZPX

is the hour angle (H), and PZX the supplement of the azimuth (A'= 180-A). A' may be computed when any three of the four parts, (p, c, z, H) are given. The latitude of the place and the declination of the body being known, the altitude of the body may be observed with a sextant, or its hour angle may be deduced by noting the time by chronometer. The problem of finding the azimuth from the altitude is called "The Altitude Azimuth;" finding it from the hour angle is called "The Time Azimuth."

1. Altitude Azimuth."—Here we have three parts, c, p, z,

$$\therefore \operatorname{Sin}^{2} \frac{A'}{2} = \frac{\sin \frac{1}{2} (p + \overline{c \sim z}) \sin \frac{1}{2} (p - \overline{c \sim z})}{\sin c \sin z}$$

or hav A'= 
$$\frac{\sqrt{\text{ hav } (p+\overline{l} \sim a) \text{ hav } (p-\overline{l} \sim a)}}{\cos l \cos a}$$

The latter formula in a logarithmic form becomes

Lhav A'=L.sec 
$$l+L$$
.sec  $a-20+\frac{1}{2}$  L.hav  $(p+\overline{l-a})$   
+ $\frac{1}{2}$ Lhav  $(p-\overline{l-a})$ .

Another convenient formula, and one easily remembered, is

$$\cos^2\frac{A}{2} = \frac{\sin s \sin (s-p)}{\sin c \sin z}$$

when 
$$t = \frac{p+c+z}{2}$$

2 "The Time Azimuth."—Here we have given three parts, c, p, H.

(a) Using a subsidiary angle  $\phi$ ,

Tan 
$$\phi = \frac{\tan d}{\cos H}$$
  
Tan A' =  $\frac{\tan H \cos \phi}{\sin (\phi - l)}$ 

(b) By the formulæ,

Tan 
$$\frac{1}{4} (A' + X) = \frac{\cos \frac{1}{2} (p - c)}{\cos \frac{1}{2} (p + c)} \cot \frac{H}{2}$$

Tan  $\frac{1}{4} (A' - X) = \frac{\sin \frac{1}{2} (p - c)}{\sin \frac{1}{2} (p + c)} \cot \frac{H}{2}$ 

$$A' = \frac{1}{4} (A' + X) + \frac{1}{4} (A' - X).$$

These put into a logarithmic form, become

Lina 
$$\frac{1}{4} (A' + X) = \text{Licot} \frac{H}{2} + \text{Licos} \frac{1}{4} (p - c) + \text{Licine} \frac{1}{4} (p + c) - 20$$

L. tan 
$$\frac{1}{4} (A' - X) = L$$
,  $\cot \frac{H}{2} + L$ ,  $\sin \frac{1}{4} (p - c) + L$ , cosec  $\frac{1}{4} (p + c) - 20$ 

$$A' = \frac{1}{2} (A' + X) + \frac{1}{2} (A' - X)$$

It should be noted that we have to decide in looking out  $\frac{1}{2}(A'+X)$  whether it is in the first or second quadrant. The required value will of course be in the same quadrant as  $\frac{1}{2}(p+c)$ .

(c) By first finding the third side z, and then from the three sides determining the angle A'.

In this process if the versine method is employed all ambiguity is avoided.

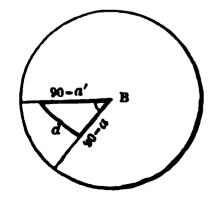

The principal practical use of the above problem is to find the correction (variation and deviation combined) of the compass.—See Compass, Corrections.

Azimuth, the Altitude.—"The Altitude Azimuth" is the problem of computing the azimuth of a heavenly body by an observation of its altitude, having also given its declination and the latitude of the place of observation; as in the case of Amplitude, this method of finding compass error should be avoided in high latitudes, since the altitude alters very slowly. In such cases the "Time Azimuth" method should be prefined.—See Azimuth, how found by Calculation. (1).

Azimuth, the Time.—"The Time Azimuth" is the problem of computing the azimuth of a heavenly body (the sun being usually chosen) from noting by chronometer its hour angle, having also given its declination and the latitude of the place of observation. Time azimuths are the more generally useful than altitude azimuths as they can be observed when a ship is in port, or when any cause prevents the horizon being defined. The process, given above, of solving the spherical triangle is tedious, and it is practically superseded by Tables or Graphic Methods, which give the results within half a degree, or less.—See Azimuth, how found by Calculation(2).

Azimuth (True) of a Terrestrial Object, how found.—
(1) By "Astronomical Bearing."—The true bearing of a terrestrial

object may be determined by means of the difference of bearing between it and a celestial body, the true azimuth of the latter being easily computed or taken from the Azimuth Tables. Let us suppose that the altitudes of the object and of a given heavenly body have been observed, and that the distance between

the object and the body has been measured by a sextant. Let d be the distance of the body and object, a and a their respective altitudes, and B their difference of bearing—then

Hav B = 
$$\frac{\sqrt{\text{hav } (d+a-a) \text{ hav } (d-a-a')}}{\cos a \cos a'}$$

Lahav B = Lasec 
$$a + \text{Lasec } a' = 20 + \frac{1}{2} \text{ Lahav } (d + \overline{a - a'})$$
  
+  $\frac{1}{2} \text{ Lahav } (d - \overline{a - a'})$ .

Knowing then the true bearing of the body and the difference (B) between its bearing and that of the object, the true bearing of the latter is easily determined.

If, as often happens, the object is in the horizon, the angle B is atill more simply determined by the solution of a quadrantal triangle.

(2) By "Geographical Position."—The true bearing or azimuth of a terrestrial object, as a mountain at a considerable distance, may be determined from its geographical position and that of the spectator. The true azimuth is the same as the course on the great circle from the spectator to the object, and this may be found by the usual rule

The true bearing so obtained will be somewhat different from what is usually spoken of somewhat loosely as the "true bearing" which is simply the course upon the illumb curve to the given point. See Mercatorial Bearing.

Azimuth Diagram, Godfray's.—A diagram by means of which the true azimuth can be rapidly and simply obtained without calculation, the data being the latitude, the sun's declination, and the apparent time. It is engraved by the Hydrographic Office, Admiralty The scale on which it is constructed gives the result to within one righth of a degree. A full explanation accompanies the diagram.

Azimuth Tables The two following works will be found most useful to the practical navigator

- 1. Sun's True Bearing or Azumuth Tables, computed for intervals of four minutes, between the parallels of 30° N. and 20° S. inclusive, with Variation Chart; also Instructions for using the Tables in Danish, Dutch, French, German, Italian, Portuguese, Russian, and Spanish. By Captain John E. Davis, R.N., F.R.G.S., of the Hydrographic department, Admiralty: and Percy L. H. Davis, F.R.A.S., Nautical Almanae Office. Price 10s 6d.
- 2. Sun's True Bearing or Azimuth Tables, computed for intervals of four minutes, between the parallels of latitude 30° and 60° inclusive. By John Burdwood, Staff Commander, R.N., late Naval Assistant in the Hydrographic Department, Admiralty. Price 4s 6d.

Asimuth and Altitude.—The horizon co-ordinates for defining points of the celestial concave in its diurnal revolution, relatively to the position of an observer on the earth's surface. Azimuth is measured on the horizon from the north or south point (that most remote from the elevated pole) westward through 360°, or westward and eastward from 0 to 180°; altitude is measured on the the secondaries of the horizon (which are hence called "Circles of Altitude") positively to the zenith, and negatively to the nadir.—Co-ordinates for the Celestial Sphere.

Azimuth and Altitude Instrument.—An instrument for taking azimuths and altitudes simultaneously. It is adapted for use on shore, as in marine surveying, the form most generally used being that called the *Theodolite*. We shall here only mention the general principle of all such compound instruments. The telescope, by which the observations are made, is capable of motion in two planes.

at right angles to each other, and the amount of its angular motion in each as measured on two circles, co-ordinate to each other, whose planes are parallel to those in which the telescope moves. In the azimuth and altitude instrument one of these planes is horizontal, the other vertical. This instrument is known as the "alt-azimuth."

Azimuth. Motion in An instrument is said to move "in eximuth" when it is turned on a vertical axis; in contradistinction, it is said to move "in altitude" when it is turned on a horizontal axis. An azimuth and altitude instrument admits of both motions.

B.

b -Among the letters used in the log-book to register the state of the weather. b denotes Blue Sky, whether with clear or hazy atmosphere.

"Backing" of the Wind.—The wind is said to "back" when it appears to shift against the sun's course. It is a sign of more wind or bad weather.

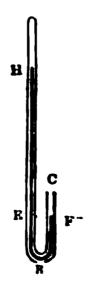

Back-staff. -A form of the quadrant for taking the altitude of the sun at sea, in use before the invention of reflecting instruments. It was the contrivance of Captain John Davis, about 1590, and was called after him, "Davis's Quadrant," but was known to the French as the "English Quadrant." It consisted of two concentric arcs, carrying at their common centre the horizon-vane; the arc of larger radius was of 25' or 30°, and carried the sight-vane. Fixed to the upper radius of this was an arc of smaller radius and of 65° or 60°, carrying the shadow-vane. The two arcs together subtended an angle of 90°; hence the instrument was a Quadrant. When taking an altitude, the observer stood with his back to the sun, and marked,

through the sight-vane on the 30° arc, the coincidence of the shadow of the vane on the 60° arc turned towards the sun, with the vane pointed to the horizon. Hence the name "Back-staff."

Barometer (Gk. \$\beta dops, "weight," "pressure;" \$\mu expels, "to-measure").—An instrument for measuring the weight or pressure of the air. It indicates whether that pressure is becoming greater or less, or remaining stationary [Atmospheric Pressure]. Theword "weight" is rather misleading. Strictly speaking, the barometer measures the elastic force of the atmosphere; with weight or density it is concerned only as they are functions of elastic force. There are two kinds of barometers.

1. The Fluid Barometer.—The discovery of the fluid barometer was the result of a question proposed by the pumpmakers to Galileo—"How is it that water will not rise in the pipe of the pump (exhausted of air) more than about 32 feet?" Galileo's pupil, Torricelli, drew practical conclusions from the fact that this 32 feet is the height of a column of water which counterpoises the weight of the atmosphere. If this were so, he reasoned that a shorter column of a heavier fluid would suffice, and experimentalized with mercury. He filled a tube about 36 inches long, and open at one end only, with mercury, and, stopping the open end with his finger, inverted the tube in an

Fig. 1.

open vessel of the same fluid. On removing the inger, the ingreaty in the tube sank to about 28 inches higher than that in the reservoir. This was the first increased barometer; date 1645. Of the different forms of the Mercurial Barometer, we shall only notice three — I. The Sighua Berometer, called so from its shape Fig. I. A tent gloss tube ABC, closed at one end, has its length as getteral position. The increasy, and is the place that a vertical position. The increasy will descend in AB, and rise in BC, leaving a vacuum above its surface in AB. Let H and F be the upper and leaver surfaces of the necessary in the two brenches;

Fig 2

draw through I tre notizental line LF. Then the pressures of the portrop of versity in the parts BF, BF balancing one another, EH is the column whose pressure or interpoises the pressure of the attor-phere, and its varying height and stee charges It. that presser 2. The Consecutor Coder's Buremeter 1 ig 2) Table consists of a vertical closed to be AR leading not an open verse' BC and a scale of irclus attac ed to AB. This is de being fixed, the height of the mercurial column indicated is the legal t above a fixed terzontal plane (O) not above the level I, of the mercury in BC, which is variable. Hence the height read off will be in error; but this error is rendered and by the area of the reservor BC being much greater than of the tube AB. The error any be easily valer lated. 3. The Marine Birometer, first constructed by M Passement in 1751. In this instrument the diameter of the recorver a about 1; mehes, and that of the tabe about ; neh. The scale, instead of being divided exactly into a sheet, as in the common barometer, is shortened in the proportion of about "14 of an

inch for every inch, which obviates the necessity of applying the error above noticed. But the distinctive feature of the marine barometer is the contrivance for guarding against the effects of the motion of the ship—the "pumping" of the mercury. The tube is contracted to a very small bore through a few inches. When first suspended, the mercury is in consequence as much as twenty minutes in falling from the top of the tube to its proper level. This contraction of the tube causes the marine barometer, when used on shore, to be a little behind the common barometer, to an amount varying according to the rate the mercury is rising or falling, being at times '02 of an inch.

11. The Aneroid Barometer.—In the aneroid barometer (the invention of M. Vidi, of Paris), the varying pressure of the atmosphere is indicated, not by the varying height of a column of fluid, but by the compression and expansion of a small metal vessel from which nearly all the air has been exhausted, and which is kept from collapsing by a spring. Hence the name (Gk. d, "without;" νηρός, "fluid"). The external appearance of this instrument is that of a circular brass box, having a dial face, the graduations of which are pointed out by a finger. This finger is moved by machinery attached to the elastic nearly exhausted vessel within. At the back of the instrument is a screw, for the purpose of adjusting its indications by reference to the mercurial barometer. The aneroid requires to be thus originally set, and should be thus adjusted from time to time. This instrument possesses the advantages of being very susceptible and portable, and is a most convenient "weather-wiser" for ship use. It is also a convenient instrument for roughly estimating the heights of mountains.

The principal use of the barometer, especially to the navigator, is that, combined with a thermometer and hygrometer, it forms a wather gloss. The barometer indicates the changes in pressure, the thermometer the changes in temperature, and the hygrometer the the changes in moisture. Combined, they give the state of the air, and this foretells coming weather. We shall here simply state the circumstances which affect the barometer (1) The direction of the wind; a northerly wind in north latitudes, and a southerly in both latitudes, tending to raise it most, and the opposite wind in each case to lower it most. (2) The moisture of the wind moisture and a falling barometer are connected; (3) The force of the wind—the greater the force the greater the fall; (4) Electricity—effects uncertain.—See Weather-Glass.

Beam.—The beams of a ship are the strong transverse timbers which stretch across from one side to the other, supporting the decks and retaining the sides at their proper distances. The greatest is called the mid-ship beam; and the beam of a ship is the term community used to describe her width.

About is in a direction drawn amidships at right angles to the beel, on the weather or the beam according to the direction of the wind Before the beam is any position of an object forward of the line about. Abost the beam is any position of an object aft of this line.

Bearing —The bearing of an object or place is in general the angle contained between the meridian and the vertical plane through the object.

Bearing. Compass.—The bearing of an object as observed by the compass. It is the angle between the needle of the standard

compass on board the ship of the observer and the direction of the object; it is therefore affected by the deviation and variation of the compass. If the correction for deviation be applied, the Magnetic Bearing is obtained; and if, further, the correction for variation be applied, the True Bearing or Azimuth is deduced.

Bearing, Magnetic.—The Magnetic Bearing, or as sometimes designated the "Correct Magnetic Bearing" of an object is the angle which its direction makes with magnetic meridian. This is the bearing which is observed with the azimuth compass after being corrected for local deviation; from it the True Bearing is deduced by applying the correction for variation.

Bearing, True.—The true bearing of an object, or the "Bearing" properly so called, is the angle which the direction of the object makes with the meridian. It is thus qualified to distinguish it from the Compass and Magnetic Bearings.—See Azimuth.

Bearings, Astronomical.—The process of finding the true bearing of a terrestrial object, by referring it to some celestial body whose azimuth is known, is described as the method of "Astronomical Bearings," which see.

Bearing, Geographical.—The method of determining the true bearing of a terrestrial object, (as a mountain at a considerable distance) from its known geographical position and that of the spectator. The problem is the same as finding the course on the great circle.

Bearing Mercatorial.—The term bearing is often used to denote the rhumb course to a given place, that is, the angle between the meridian and the rhumb line passing through the place. Thus

the bearing of a terrestrial object as taken from the Chart will differ from that found from reference to a celestral body, and described as the Astronomical Bearing

Bearing, taking a .- Taking a bearing of an object is technically called "setting" the object.

Bearing Plate -Bearings should always be taken on board ship when possible by the Standard Azimuth Compass. Sometimes however the all-round view from the compass is interfered with by fittings in the ship, or the compass may be below as in Second Class Torpedo boats. In such cases the simple instrument commonly known in the Service as a Bearing Plate is of great assistance. Ita seental feature is a card to all appearance the same as that of the compass, but without magnetic needles of any sort. This is hung and balanced precisely like the card of the compass, so as to retain a horizontal position, and furnished with azimuth vanes, and is adjusted with its lubber's point exactly parallel to the fore and aft line of the vessel. Not being magnetic the instrument is unaffected by the iron in the vessel, and may be placed in a convenient position in any part where the observation of the bearing of the object is not interfered with. The degree on the Bearing Plate indicated by its lubber a point should correspond to the compass course of the vessel we shewn by the Standard compass or other compass used. the thip's head is exactly on the course, an assistant observer at the compass calls "Stop," and the observer at the plate notes the bearing of the object at the same matant. The following is the description of a simple form of bearing plate from the Elementary Manual for the Demation of the Compous in Iron Ships, 1895.

"A circular plate of brase with a raised ring of four to eight make diameter, upon which the lubber point is marked, is suspended

on gimbals, and weighted so as to remain horizontal when the ship rolls. The gimbal ring is mounted on brass supports fixed in a square box, which can be placed on a fixed pillar or in any required position. The space included by the raised ring is fitted with a brass plate marked as a compass in points and degrees, and movable round the fixed centre pin of the brass plate. Outside the raised ring is a movable circle carrying the sight vanes as in an ordinary azimuth compass, with a pointer for reading off the bearing."

## See Compass-Card Dumb; Pelorus.

Bearings, Cross.—"Cross Bearings" are the bearings of two or more objects taken from the same place, and therefore intersecting or "crossing" each other at the station of the observer. When near a coast where the landmarks are well laid down on the chart, cross bearings give the position with ease and accuracy.

Bearings, Reciprocal.—The bearings of two compasses each taken from the other.—See Swinging the Ship.

Bearing. Line of.—If a ship is in the vicinity of land, one "Circle of Equal Altitude" is often of great use to the navigator who is uncertain of his exact position. He is on some point of this circle, but where he does not know. Let him project it on his chart and produce the resulting line till it meets or passes near the land. Such a line is called a "Line of Bearing." If the line strike any prominent mark or light, the bearing of this is known, and by sailing along the line of bearing till the object is sighted, the exact position of the ship may be picked up. The line of bearing may cross the range of a lighthouse, and consequently when the light is first sighted, the exact position of the ship is known. Or the

BOOTES.

position of it on the line of bearing may be found by soundings. When the coast trends parallel to the line of bearing, the distance of the ship from the shore is indicated, though her absolute position is uncertain. See Sumner's Method.

Bellatrix (L. " warhke").—The name for the bright star  $\gamma$  Octons. See Orion.

Betelguese or Betelgeux, -The name for the bright star a Orion. See Orion.

Binnacle (formerly Bittacle, from Bitts). The turret like cover to the compass on deck; it is glazed and furnished with suitable tamps. The "Binnacle Compass" is often the name used for the compass placed in a commanding position, at which the pilot stands to "con" the vessel, in contradistinction to the "steering compass," which is situated before the heliusman. There is, however, a binnacle-cover for all the compasses.

Bissextile (L. bis, "twice;" sextus, "sixth"). -"Leap Year" In the Julian calendar every fourth year consiste I of 366 days, instead of 365. The additional day was intercalated or inserted after the 24th of February, which in the Roman calendar was reckoned as reconstructed March," the sixth day before the Calends of March," every fourth year this day was repeated as the bis sexto ("mendia March, the added day being called the bissextus dies. The year was hence named Bissextus.

Bootes , (.k powrys, "a ploughman").—The name, as an ient in the Homeric age, of the constellation following the Great Rear, which, it is probable, was originally figured as an ox or waggon. However is also called Arctophylax, "the Bear watcher;" and the one bright star in the group, a Bootis, is named Arcturus, which has a untilar meaning, "the Bear-Keeper." a Bootis can easily be found

by continuing the curve formed by the three stars of the Bear's mail to about twice its length. It is one of the stars observed to have a proper motion. Mag. N A 1896 0.0; R A 14h 11m, Dec. + 19° 43'.

Borda's Circle.—A repeating reflecting circle, constructed by the eminent French surveyor Jean Charles Borda (died 1792). Borda introduced into the French naval surveys the use of reflecting instruments, instead of determining positions by compass bearings. He improved upon Mayer's Reflecting Circle, and invented the "principle of repetition." Theoretically this method of observing reduces the effect of errors of graduation of the instrument to any extent, but there is some practical obstacle to any satisfactory realization of this result —See under Circle.

Bore (a word imitative of the sound produced, like the Anglo-Saxon To bore. Compare the other names for the phenomenon-French, Barre; Brazilian, Pororoca; English, Eagre or Hygre; Dutch, Agger. Sometimes the word is written Boar or Boar's Hear, and then an analogy to the rushing career of that animal is suggested.) —The form the tide-wave assumes at spring-tides in certain estuaries and rivers. As the tide enters and advances the wave acquires a considerable elevation, with an abrupt, broken face, and rushes up violently against the current with a hollow and harsh roar. other places the phenomenon is seen in the Severn, the Garonne, and the Bay of Fundy. In some of the rivers of Brazil this tide-wave rises to the height of from 12 to 16 feet, and in the Hooghly it travels at the rate of above 17 miles an hour. The conditions necessary for the formation of the bore are :-First, a very large tide rising with great rapidity; and secondly, that the river be bordered with a great extent of flat sands near the level of low water, the channel contracting gradually from an estuary. Attention to the bore in different places is of great unportance to the seaman in anchoring ships and in boat duties. Thus no boat ventures to navigate the channels between the islands at the mouth of the Brahmapoutra at spring tide; in the Hooghly, at Calcutta, the bore running along one bank only, on its approach the smaller shipping are removed to the other side, or ride it out in mid stream; and in some of the rivers of Brazil the barges, at the spring-tides, are always moored in deep water, it being noticed that the bore is only dangerous on the shoals.

Breakers -Waves whose creats are broken. They are among the signs of the near approach to land. The depth of water, however, at which they appear is uncertain, and it is often difficult to distinguish between breakers and "topping seas."

Boxing the Compass.—Repeating the points of the compass in order.

Buys-Ballot Law —The law of wind rotation as extended by Buys Ballot. It is as follows: If there be a difference between the barometric readings at any two stations, the wind will blow at right angles to the line joining them; the observer with his back to the wind will have the place where the reading is lowest on his left hand aide in the northern hemisphere, but on his right-hand side in the southern hemisphere.

C,

c.—Among the letters used in the log-book to register the state of the weather, C denotes "cloudy" i.e. detached opening clouds

Cable. —As a measure used in marine surveying a cable is one tenth of a nautical mile, which is estimate roundly at 6000 feet. Thus, I cable = 100 fathoms = 600 feet.

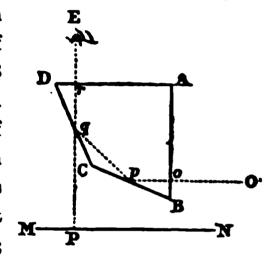

Calendar (L. Calendarium, Calenda, the first day of each month, from caldre, "to call," "summon"), - The regulation, arrangement, and register of civil time. The ancient Roman calendar is the original of those used throughout Europe. natural unit for shorter durations adapted to the immediate wants and ordinary occupations of man is the solar day, or period of the sun's successive arrivals at a given meridian. It varies in length during the course of a year, but the variation is socially unimportant, and the tacit adoption of its mean value from the earliest ages arose probably from ignorance that such fluctuation existed. This mean solar or civil day is divided into 24 hours. The unit for longer durations again is naturally the period in which recur the scasons on which depends all the vital business of life. It is the interval between two successive arrivals of the sun at the vernal equinox, and is called the tropical year. This period varies slightly, and is incommensurate with the lesser unit, its length being about 365d 5h 58m 59 7. Now if the odd hours, minutes, etc., were to be neglected, and the civil year made to consist of 365d, the seasons would soon cease to correspond to the same months, and would run the round of the whole year; this odd time must therefore be taken account of. But then, again, it would be very inconvenient to have the same day belonging to two different years. To obviate this difficulty, a very neat contrivance was mangurated by Julius Casar by the mivice of the astronomer Sosigenes. He introduced a system of two artificial years, one of 365 and the other of 366 integer days; three consecutive years consisting of 365, and then a fourth year of 366 days. The odd months each consisted of 31 days, and the even months of 30 days, except February, which had only 29 days; on every fourth year February also had the regular 30. This simple arrangement was

soon disturbed, in flattery to Augustus, by assigning the same number of days to the mouth named after him as was contained in that named after Julius Clesar. The longer years were called "bissextile or ." leap-years," and the surplus days formed of the accumulated fractions and thrown into the reckoning were called ' intercalary" or "leap-days." This calendar made the average length of civil years 365d 6h, which was only a rough approximation to the truth, and the error soon accumulated to a whole day. A reformation was effected by Pope Gregory XIII in 1582 He suppressed 10 days of she calendar, thus restoring the vernal equinox to the 21st March, the day on which it fell at the date of the Council of Nice, 325 law for the future regulation of the succession of the short and long years is as follows :- Every year whose number is not divisible by 4 without remainder consists of 365 days; every year which is so divisible, but is not divisible by 100, of 366 days; every year divinible by 100, but not by 400, again of 365; and every year divisible by 400 again of 3.6 days. It may be conveniently remembered thus .- Every year whose number does not end with 00 and is divisible by 4 is a leap year, and every year whose number ends with 00 and is divisible by 400 is a leap year. The error in the Gregorian reckoning amounts only to one day in 3800 years For the period of 10,000 years the average length of the Gregorian years is 365-24254 (according to Delambre's tables). The Protestant countries of Europe were long before they adopted this reform, and it was not introduced into England till 1752. The "old style" was then abolished by Act of Parliament. The rectification was effected by dropping It days and enacting that the day following 2nd September, 1752, should be called 14th September

Camera Lucida. (L." Light chamber").—An instrument for making the image of any object appear on a wall in a light room

either by day or night. With suitable appliances it enables any one who can manipulate it, to trace with perfect accuracy the outlines of distant objects such as landscapes. The essential part is a quadrilateral prism of glass, by means of which rays of light are bent by two reflections from its inner surface into a path at right angles.

will explain this. ABCD is a section of the prism at right angles to the axis; AB and AD are equal, A is 90°, C 135°, and the angles B and D each 67° 30′. A ray of light, entering the face of the prism perpendicularly at o will continue its straight course till it strikes the adjacent face at p, making with it an angle of 22° 30′;

it is therefore reflected from the inner surface of the denser medium in the direction p q, striking the next face at the same angle at q, where it is again reflected in the direction q r emerging at r at rightangles to the prism. An eye situated at E sees the image of the object in the direction E q and refers it to P on a plane M N. See-Prism; Reflexion.

Cancer, Constellation of (L. Cancer "The Crab").—The fourth constellation of the ancient zodiac, lying between Gemini and Leo. There is no star in it above the fourth magnitude.

Cancer, Sign of.—The fourth division of the ecliptic, including from 90° to 120° of longitude. Owing to the precession of the equinoxes, the constellation Cancer is no longer in the sign of the name, the constellation Gemini having taken its place. The sun is in Cancer from about June 21st, when he arrives at his greatest.

61

northern declination, to about July 22ml. The First Point of Cancer is known as the summer solstice in the northern hemisphere. Symbol 2.

Cancer, Tropic of.—That parallel in the northern hemisphere whose bititude is equal to the sun's greatest declination, about 23° 27'.

Canes Venatici (L. "The Hunting Dogs"). —A constellation between I rea Major and Bootes. The two dogs are named Asterion and Chara. The principal star is marked a Canum Venaticorum, named also Cor Caroh, and may be found by drawing a line from Dubbo, the star of the Great Bear nearest the pole, to the opposite star of the square of that constellation, and producing it to nearly twice the distance. Mag. 3. N. A. 1896; R. A. 12° 51m. Dec. + 38′ 53′.

Canis Major (I. "The Greater Dog") —A constellation to the S.F. of Orion, containing the brightest star in the heavens, a Cana Majoria, the Dog Star, is also called Sirius; it can easily be found by continuing the line of the belt of Orion to about three times its length—Mag. - I 4 N A, 1896, R.A. 66 41m, Dog.—16° 34'.

Canis Minor (L. "The Lesser Dog").—A constellation to the E. of Orion, containing a bright star, a Canis Minoris, called also Process. It can be easily found by continuing a line through the upper two stars of Orion to about twice its length. Mag. 0.5 N.A. 1896; B. A. 7. 344, Dec. +5° 29'

Canopus.—The name of the bright star a Argus. Called after place in Egypt.—See Argo.

Capella (L. "The Kid").—The name of the bright star a

Capricornus, Constellation of (L. Capricornus, "The Goat").—The tenth constellation of the ancient zodiac, lying between Sagittarius and Aquarius. There is no star in it above the third magnitude; a and  $\beta$  may be found by the line joining Lyra and Altair being produced to not quite its own length.

Capricornus, Sign of.—The tenth division of the ecliptic, including from 270° to 300° of longitude. In consequence of the precession of the equinoxes, the constellation of Capricorn is no longer in the sign of this name, the constellation Sagittarius having taken its place. The sun is in Capricorn from about December 21st to about January 20th. The First Point of Capricorn is known as the Winter Solstice in the northern hemisphere. Symbol &.

Capricorn, Tropic of.—That parallel in the southern hemisphere whose latitude is equal to the sun's greatest declination, about 23° 27'.—See Tropics.

Cardinal (L. cardinalis, literally, "pertaining to a hinge," cardo, hence that on which other things turn, "principal").—The points to which, as regards position and motion, others are referred. Thus we have "the Cardinal Points of the Compass," "the Cardinal Points of the Ecliptic."

Cardinal Points of the Compass—The same as the cardinal points of the horizon, named with reference to the direction of the magnetic needle. They are called *North*, *South*, *East*, and *West*; the most important of which is the North.

Cardinal Points of the Horizon.—The four cardinal points of the horizon are the North (N.), South (S.), East (E.), and West (W.). The north and south points are those in which the meridian intersects the horizon, and they are the poles of the prime

vertical; the east and west points are those in which the prime vertical intersects the horizon, and are the poles of the meridian. The north and scuth points are those from which the horizontal distance from the meridian of all bodies having an altitude is measured; the east point is that to which their rising, and the west point that to which their setting is referred.

Cardinal Points of the Ecliptic -The four cardinal points of the ecliptic are the two points of its intersection with the equinoctial, called the Equinoctial Points, and the two points where it attains its greatest distance from the equinoctial, called the With reference to the seasons of the northern Solatitial Points bemusphere, these are named the Vernal and Autumnal Equinoctial Pante, and the Summer and Winter Solstitud Points. These are more commonly called after the signs of the ecliptic in which they are severally situated; the First Point of Aries (symbol T) and the First Point of Libra (A), the First Point of Cancer (2) and the First Point of Capricorn ( ). The Colures intersect the ecliptic in these four points. The most important of them is the First Point of Aries, so from it right ascensions and longitudes are reckoned. The sun is in T about March 21st, in a about June 21st, in a about September 21st, and in 17 about December 21st.

Cassiopeia (named after the mythical wife of Cepheus).—A constriction on the opposite side of the pole to the Great Bear, and at about the same distance from it. It consists of a group of stars of the third and fourth magnitude, disposed in a form somewhat resombling a chair, or the letter W. a Cassiopeia is, of the six principal stars, the furthest from the pole. Mag. variable, limits 2.2 and 2.8, N.A. 1896; R.A. 0h 35m, Dec. + 55° 58°.

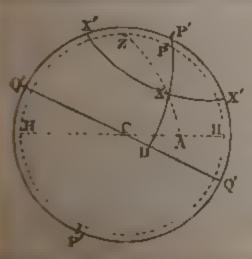

Castor.—The name of the bright star a Geminorum.—See Gemini.

Celestial.—(L. Calestis, from calum, "the heavens").—
Pertaining to the heavens; opposed to terrestrial, pertaining to the earth. Thus we have the "celestial meridian" of an observer, and the "celestial horizon," as distinguished from his "terrestrial meridian" and "terrestrial horizon;" the "celestial equator," as distinguished from the "terrestrial equator;" "celestial longitude and latitude," and "terrestrial longitude and latitude."—See under each noun qualified.

Celestial Concave (L. concavus, "hollow").—Of the two spherical surfaces with which we are concerned, the terrestrial sphere is convex—i.e. presents its external surface to us; while the celestial sphere is concave—i.e. presents its internal surface to us. The latter is an imaginary surface. The different heavenly bodies are interspersed in space at various distances from the earth, but to a spectator on its surface all of them appear (in consequence of the constitution of our organs of vision) to be placed or projected on the interior surface of a hollow sphere of infinite magnitude, its centre being the centre of the earth, which is considered coincident with the position of the observer This is called the "Celestial Concave." the "Sphere of the Heavens," or "Sphere of the Stars." always be remembered that the spherical dome above us exists in appearance only, arising in the mind of a spectator of the heavens from association with the real concave surface of the retina of his eye, which is the true seat of all visible angular dimensions and angular This celestial concave, with its radius infinite compared with all terrestrial distances, is a confusing conception when problems are concerned. But all ambiguity will be dispelled if we bear in

mind that Nautical Astronomy is concerned not with actual but with angular distances of the heavenly bodies; plane and dihedral angles subtended at the eye being involved. The only purpose the celestral concave subserves is that it enables us to substitute spherical triangles for solid angles. The radius of this sphere is perfectly arbitrary, and may be taken great or small, the eye of the spectator being supposed, as he changes his position, to occupy the centre. This point is fully explained in a paper by the Author in Naval Science, January, 1873, "The Definitions of Nautical Astronomy systematized."

Celestial Concave, Motion of.—With respect to the motion of the celestial concave, its points and circles fall under two divisions—those which are dependent upon the observer's position, and those which are the same wherever he is stationed. To meet the difficulty thus created, we may imagine an inner transparent surface to the celestial concave in rigid concetion with the earth, on which, projected from the centre of the earth C, are the observer's station giving us the zenith Z, and the great circle of which it is the

pole—the horizon HAH. The position of Z determines also the meridian ZPH of the observer. All these are considered as fixed with the observer, and marked down upon the inner transparent shell of the celestial concave. On the outer surface all those points (the stars, centre of sun, etc., and imaginary circles connected with them)

are projected which are independent of the observer's position; and this surface is conceived to revolve diurnally about its axis PP, carrying with it these points and circles, and causing them to sweep across the points and circles of the inner fixed surface. These fixed circles are what are represented by the broad horizontal wooden rim and brazen meridian of the old artificial celestial globe, and by the metrosphère of modern French navisphère.

Celo-Navigation (L cælum, "the heavens," from Gk. κοίλον, "hollow").—A term I have proposed for that branch of the science of navigation in which the place of a ship at sea is determined by finding the zenith of the place from observations of the heavenly bodies. The other branch, in which the position of the ship is determined by referring it to some other spot on the surface of the earth, we distinguish as Geo-navigation. There is some difficulty in deciding upon the best prefix for this much-needed term. Urano (Gk οὐρἄνὸς, "the vault of heaven") would be more critically correct as antithetical to Geo (Gk.  $\gamma \bar{\eta}$ , "the earth"), as in the terms "geography" and "uranography," but the resulting compound Gk. (dorpa, "the stars"), would be inconvenient. Astra the prefix of "astronomy," suggests itself, but this reference to the heavenly bodies, whereas we are concerned also with imaginary points of the celestial concave. The only objection to celo is that it is directly derived from the Latin, while that to which it is opposed, geo, is directly from the Greek; but, besides that this Latin word is of Greek origin, this slight objection is outweighed by the appropriateness and brevity of the prefix, analogous to the familiar term, "celestial concave." What we here distinguish as Celonavigation has hitherto been commonly known as "Nuutical Astronomy." The term "nautical astronomy," however, implies a being of the science of astronomy, just as "nautical geography" weed i mayly a branch of the science of geography; whereas we are speaking of a tranch of the science of invigation.—For fuller potter of (ch may getten, see under Navigation.

Centaurus (L. "The Centaur") —A constellation which, together with Crick, constitutes a bright group in the southern being here, pointed out by the line joining Arcturus and Spica. The two primpulsters, or and 3 of the Centaur, are close together.

51- ag the nearer to the cross—a" Centauri Mag 0.7 N A 1896; R.A.

14 23 Dec. 60" 24 S Centauri, Mag 1.2 N A 1896; R.A. 13a

55- 16. 50-52"

Centigrade 1. comm, "a hundred;" grades "a step,"
"grades "a A centigrade scale is one in which the unit is
divided into a hundred e-man parts or grades. The term is best
known as applied to tels, as a therefore eter, which is graduated with
a hundred discess between the freezing and boiling points.—See
Thermometer.

Centimètre (L. ..., ..., "a handred," Fr. mêtre). -A French mean of the method handredth part of the metre, and equal to 304, or about 1 of the legish met. - St. Mètre.

Central Latitude. The angle which the line joining the station of the observer with the "centre" of the earth makes with the plane of the equator, as distinguished from the angle which the vertical line at the place makes with the plane of the equator. The more confirmally recognized term for this is "Geocentric Latitude," but there are reveral objections to it. In speaking of terrestric latitudes, the grows redundant; and again, the adjective geocentric,

in opposition to heliocentric, is applied to celestial latitudes, and it would be well to restrict it to so appropriate a usage. We prefer the terms central and normal latitude.—See Latitude of an Observer.

Central Projection of the Sphere.—A natural projection on a tangential plane as primitive, the eye being at the "centre" of the sphere. It is also called the "Gnomonic Projection."—See Projection.

Cetus (L. "The Whale").—A constellation to the south of Aries. It contains two principal stars a and β. a Ceti, called Menkar, is in the vertex towards the S.W. of an isosceles triangle, at the angles of whose base are the Hyades and Pleiades. Mag. 2.7. N.A., 1896; R.A. 2h 57m Dec. +3° 41′. β Ceti is found by joining Aldebaran and Menkar, and producing the line to nearly twice the length. Mag. 2·1 N.A. 1896; R.A. 0h 38m, Dec. – 18° 33′

Chain.—The unit employed in the actual measurement of lengths by surveyors. The land-surveyor's or Gunter's chain consists of 100 links=4 poles=22 yards=66 feet. The marine surveying chain, which is also sometimes used by builders, is 100 feet in length.

Change of the Moon.—The phenomenon which takes place when the moon and sun are in conjunction, at which time the moon commences afresh to go through its phases. The term is sometimes loosely applied to the transition from any one quarter to the next.—See Lunation.

Change Tide.—The tide, high water of which takes place on the afternoon of the day the moon "changes" or is at the full, more especially if the moon happens to change at noon, or is full at midnight.—See under Tide.

Chart (L. charta, from Gk. xaprm, "a leaf of paper ) -The map of the hydrographer Navigation would be impossible without the chart, and its construction has especial reference to the requirements of the navigator. The use to be made of the chart in each case determines the method of projection, and the particulars to be inserted (1) Thus the chart may be required for coasting purposes, for the use of the pilot, etc., and then, only a very small partion of the earth's surface being represented at once, no practical error results from considering that surface a plane, and a "pure chart" is constructed, in which the different Leadlands, lighthouses, etc., are laid down according to their bearings. The soundings are marked in these charts with great accuracy; the rocks, lands, and shouls, the channels with their buoys, the local currents, and creumstances connected with the tides, are also toted (2) Again, for making long sea passages, the navigator wants a chart on which his course may be conveniently marked down. Now if he mails for any time on the same course, which is a practical accessity, be describes a thumb curve on the earth's surface, and this curve is represented by a straight line (and can therefore be at case hown with a rule) on the " Mercutor's chart." Hence this is the proje tion of main unportance in navigation (3) Where great circle sailing is pract alde and advantageous, a chart on the "central propertion" exhibits the track as a straight line, and is therefore convenient

bor a short history and description of the charts on which the ancientor projects the position and track of his ship, see a paper by the author in Naval Science, July, 1872, "Rhumb and Great Craft Charts."

Besides these charts, in which the geographical features are mostly, the navigator uses would charts, current charts, majnetize

charts, passage charts. These are all most useful to him when on Mercator's projection.—See under Winds, Currents, Magnetism, Passages.

Chronometer (Gk. χρόνος, "time;" μετρείν, "to measure").— A watch of superior construction used for purposes where an accurate account of time is required—by the navigator to determine his longitude. Like the common watch, it has for its moving power a mainspring, but the force of this is rendered uniform by a variable The principal characteristic of its construction is the lever. for compensating for the effects of changes of A change of temperature, causing expansion and temperature. contraction in the different parts of the mechanism, is the chief cause of irregularity of watches, and a navigator carries his watches through all varieties of climate. The chronometer is therefore furnished with an expansion balance, formed by a combination of metals of different expansive qualities (as brass and steel), which effects the compensation required. Another cause which affects the regularity of watches is any violent action to which they may be subject, such as the jerks and vibrations of a ship. Electricity and magnetism are also said slightly to influence them. These sources of irregularity may in a great measure be guarded against by proper treatment of chronometers on board ship. The temperature of the chronometer-room may be regulated by lamps; they may be defended from violent motion, by their cases being lined with cushions of soft wool, and by being preserved in a horizontal position by suspension in gimbals; and care should be taken to wind them up at regular intervals. No chronometer, however, can be made absolutely perfect, so as not to be influenced by disturbing causes; the

unvigator, therefore acknowledges the want of perfection, and directs his attention to determine the resulting error, and to detect any variation in the going of his timepiece.

The best English work on Chronometers is "Notes on the Management of Chronometers and Measurement of Meridian Distances," by Admiral Sir Charles Shadwell, K.C.B., F.R.S. Published by J. Potter, 31, Poultry, London.

The articles which follow are arranged, not in an alphabetical, but in a natural, order.

Ohronometer, Standard.—The chronometer upon which, of all on board, most dependence can be placed. It is best, however, simply to consider it in the light of that with which, for convenience the rest are compared, and to which all observations involving time are, in the first instance, referred.

Ohronometer, Observation.—Commonly called the "Deck" or "Hack Watch." A small portable chronometer (as distinguished from "box chronometers" used for taking the time of observations. It should always be compared immediately before and after an observation with the standard chronometer.

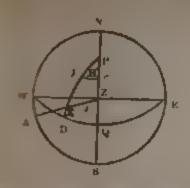

Chronometer, Error of. -"The Error of Chronometer on Mean Time at any place" is the difference between the time indicated by the chronometer and the mean time at that place. "The Error of Chronometer on Mean Time at Greenwich" is the difference between the time indicated by the chronometer and the mean time at tireenwich. The error is said to be fast or slow as the chronometer is in advance of or behind the mean time in question. Before sailing a navigator is supposed to know the error of his chronometer on

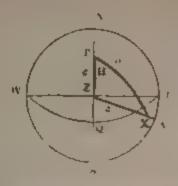

Greenwich mean time; and it is of vital importance that he should be able constantly to determine this error. The problem is simply how to find the mean time at any place. The difference between this time and the time indicated by the chronometer gives its error on mean time of the place; the Greenwich mean time is deduced by applying the longitude in time to the mean time of place of observer, and hence the error of the chronometer on Greenwich mean time can be found. The following are the methods usually adopted for finding the error of chronometer:—

- 1. The sidereal clock of an observatory gives us sidereal time at any instant at the station, from which mean solar time may be deduced with the aid of the tables of Time Equivalents given in the Nautical Almanac. The institution of time-balls renders the clocks of observatories available to the public, and ships while lying in most of our principal ports may thus obtain the error of their chronometers on Greenwich mean time.
- 2. With a portable transit instrument. The instant when a heavenly body passes the meridian may be observed by this means.

  (1) A star's transit. The right ascension of a star is the same as the sidereal time at a place at the instant when the star is on the meridian of that place; and from this the mean time may be deduced.

  (2) The sun's transit. When the sun's centre is on the meridian it is apparent noon at the place, so that, by applying the equation of time, the mean time may be deduced.
- 3. With sextant and artificial horizon; observation of a single altitude of a heavenly body when not too near the meridian. This altitude (AX=a), with the declination of the body (DX=d), and the

tatitude of the place (QZ-l) enables us to compute the hour-angle (H) of the body. Let z 90 a, p  $90\pm d$ , c 90 l; then in the triangle PZX we have the three sides to determine the angle H, which may be done by one of the formule:—

(a) 
$$\cos^2 \frac{H}{2} = \frac{\sin s - \sin (s - z)}{\sin p - \sin r}$$
  
When  $s = \frac{z + p + c}{2}$   
(b)  $\sin^2 \frac{H}{2} = \frac{\sin \frac{1}{2} (z + p - c)}{\sin p - \sin c}$   
(c) hav  $H = \frac{\sqrt{|\ln x|} (z + l \pm d) \ln x - (z - l \pm d)}{\cos l \cos l}$ 

 $\ell \ell \pm \delta$  seconding as  $\ell$  and  $\delta$  are of different or same names). Hence Lihav H. = L. sec d + L, sec  $\ell + 20 + \frac{1}{4}$  Lihav  $(z + \ell \pm d)$ 

(1) If a star is the body observed, the hour-angle, with the R.A. of the star, gives siderest time, from which mean time can be found.

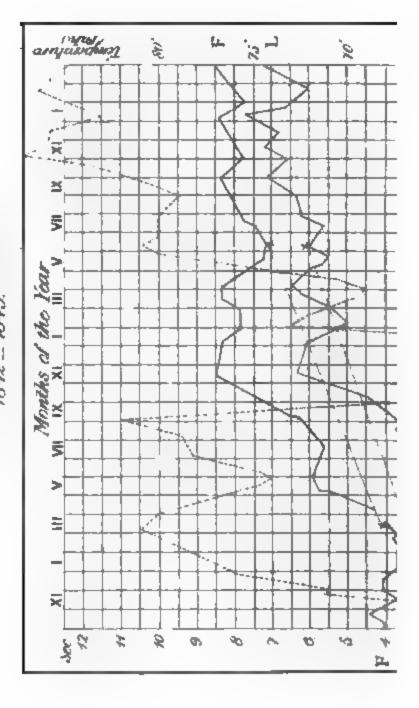

(2) If the means the body observed, the hour-angle gives the apparent time, from which mean time can be deduced.

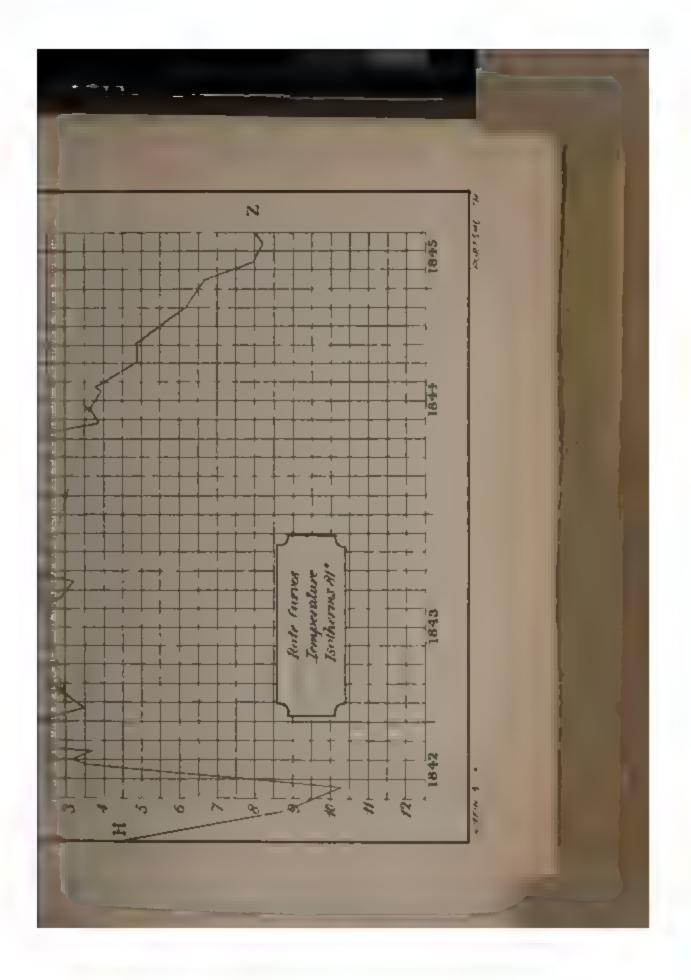

4. With sextant and artificial horizon; observation of "equal altitudes." (1) A star observed. The declination of a star is invariable between the two observations of equal altitudes, and therefore the same altitude corresponds to the same hour-angle on each side of the meridian, and the middle point of time between the instants of two equal altitudes is the instant at which the body passes the meridian. Having thus the time by watch, if from R.A. of Star or subtract R.A. Mean Sun, we have Ship Mean Time of Transit. Comparing the time shewn by watch at transit with the local mean time so obtained we have the error of chronometer, fast or slow on local mean time. (2) Sun observed. If the sun's declination, like a star's, were invariable, the mean of the observed times of equal altitudes, A.M. and P.M., would be apparent noon. But in the interval the sun sensibly changes its declination, and hence the necessity for a correction, which is called the "equation of equal altitudes." This being applied, the chronometer time at apparent noon is accurately obtained, and hence at mean noon.

Chronometer, Rate of.—The rate of a chronometer is the daily change in its error, or the interval it shows more or less than twenty-four hours in a mean solar day. If the instrument is going too fast, the rate is called gaining; if too slow, losing. The rate is obtained by determining the error of the chronometer on mean time at the same place on different days by some one of the methods used for that purpose. If the error is found to remain unaltered, there is no rate; if it is observed to change, we know from the amount of that change and the time elapsed how much it gains or loses in twenty-fours i.e. its rate. If possible, the error should be taken on successive days, at the same hour. A chronometer is best rated at

•

•

•

an observatory Before going to sea it is necessary for the navigator to know, in addition to the error of his chronometer on Greenwich mean time, its rate

Chronometer, Sea-rate of.—The rate of a chronometer deduced from the change in its error during a sea passage. When a ship leaves a place, and after an interval of not more than a fortnight returns to it again, the error of the chronometer is determined at her departure and on her return. The difference between the two, divided by the interval elapsed, gives the sea rate, which will in general be found not to be the same as the rate would have been had the ship remained in harbour between the two observations, and it is evidently of more value.

Ohronometer Journal. The book kept for the daily record of the comparisons of the chronometers on board ship. There are several forms in use, but all vessels in H.M. service keep and return the official one approved by the Admiralty; it may be found in the Admiralty Instructions. Besides the "Chronometer Journal," a "Chronometer Sight Book" and "Chronometer Work Book" are most desirable.

Chronometer Diagrams.—The Chronometer Journal may be embodied in Jiagrams, though their utility has not been as yet generally acknowledged by English navigators. Their construction has been investigated in France by Mons. E. Mouchez, and by M. A de Magnac. Specimens of Feuilles Mensuelles and Feuilles Annuelles may be found in Cours de Navigation et d'Hydrographie, par E. Dubois.

I wrote a short article on "The Chronometer Journal in Diagram" in The Nautical Magazine, September, 1866, and then proposed two methods for depicting the comparative or relative rate curves; and I

discussed the whole subject in a paper—"Chronometer diagrams"—in Naval Science, January, 1875. The substance of these articles is given here, as the requisite imformation for the construction of diagrams is not easily accessible to the majority of navigators.

The curves are of two kinds, absolute rate curves and relative rate curves. Both are projected on a simple form similar to those used for thermometer and barometer diagrams. On a sheet of cross-ruled paper the abscissæ will represent the times and the ordinates the rates. The region above the zero line is considered positive, and that below negative. The examples given below are all taken from actual Chronometer Journals.

## I. Absolute Rate Curves.

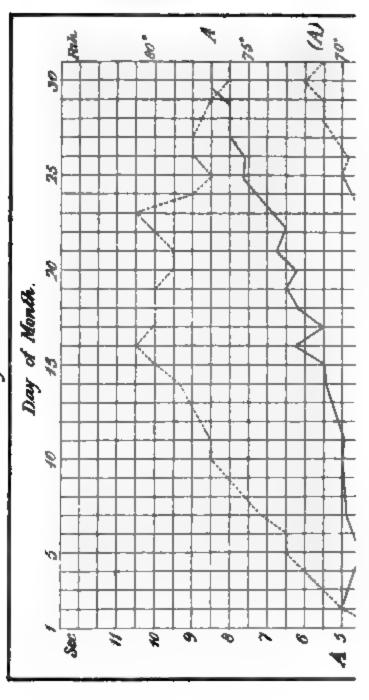

When the absolute rate of a chronometer is deduced from time to time by a comparison of the errors determined from observations, there is no difficulty in marking off the errors corresponding to different dates. By joining the points so obtained, the fluctuations in the rate will be graphically represented by a curve. On the same diagram may be drawn the absolute rate curves of all the chronometers on board; and if this be kept marked up throughout a ship's commission, it will exhibit a very palpable picture of the idiosyncrasy of each watch. The two circumstances which chiefly affect chronometers over a long period are, lapse of time, and changes of temperature. Many chronometers exhibit a very regular tendency to a gradual acceleration of rate, as time advances, since they were last adjusted; and there is generally a tendency to an increase of gaining rate upon a decrease of temperature.

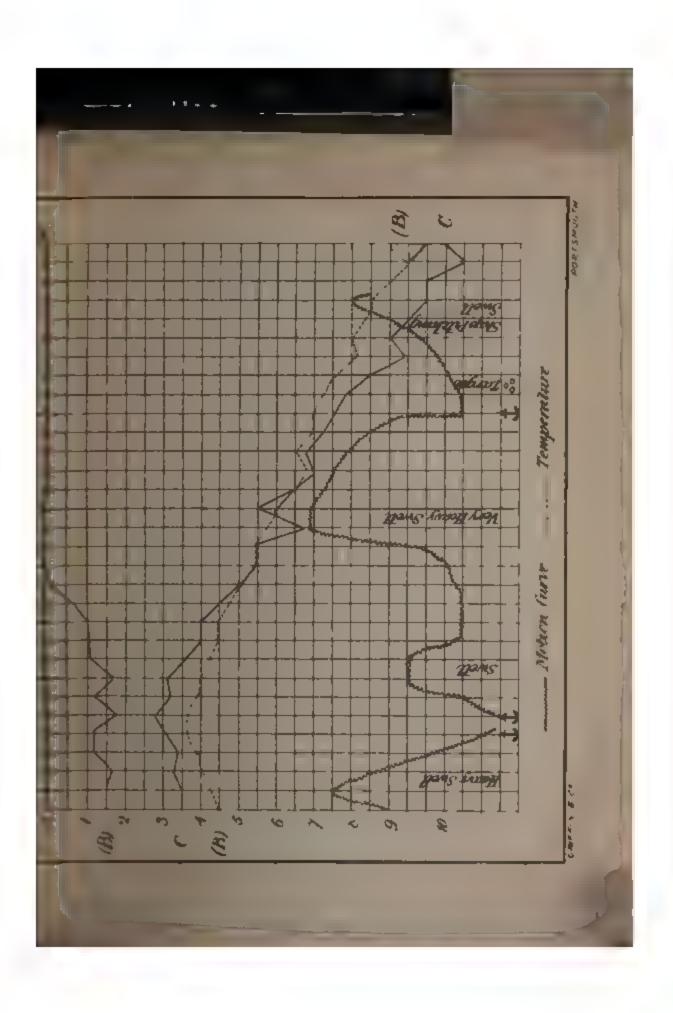

Diagram No.1 gives a portion of the absolute rate curves of four of the Chronometers (Z, F, H, L.) of H.M.S. "Fly," employed in surveying the coast of Australia, in 1842—1846. It is constructed

		•

CHRONOMETER DIABRAM Nº 2.

RELATIVE RATE CURVES. H.M.S. Frying Pish, England to Cape of Good Hape. August., 1874.

om the table given in Shadwell's "Notes on the Management of aronometers," pp. 224, 225. This diagram is on a much smaller ale than should be practically used for so long a period, a whole both being included between the vertical lines. The effects of the pse of time may be isolated by drawing isotherm lines. In the care the isotherms of 81° are drawn, covering a period of fifteen on this; and they show that the rates of watches F, H, and L were believed by the lapse of time, and that of Z retarded. A sudden I of temperature, within the period of two months, from \$2° to 62° a marked effect, as, during this interval, the gaining rates were creased from 2s to 3s for all the four chronometers.

## II RELATIVE RATE CURVES.

There are two methods of drawing the comparative or relative to curves. In both, the vertical columns represent successive days, if the horizontal columns, differences of rates of 1s or 5s, as found cessary. In the first method, no standard chronometer is knowledged, the judgment being left unbiassed, and every renometer being valued according to its behaviour; in the second othod, an imaginary mean chronometer is regarded as the standard, and to the irregularities of this all the chronometers contribute. The latter method was suggested to me by my college friend, the Mr. Hugh Godfray.

## (1) First Method.

A dark horizontal line is taken as the zero line, from whence the linates denoting the daily differences of the chronometers, taken and two together, are measured, the region above being eldered positive, and that below negative. On any given day, sum of the ordinates is equal to zero, this check always holding

good. Each curve, then, depicts the fluctuation in the combined rates of the two watches compared, i.e. the daily difference of the differences of the pairs A and B, B and C, C and A. It is probable that the irregularities in the curve which exhibits the comparison of A and B will be caused chiefly by the fluctuations in the rate of one of them. A or B, and similarly for the others. The more irregular a curve, then, the greater the probability that one of the watches involved is going badly. Hence, if we name each curve by the watch not involved, writing the distinguishing letter in brackets, as (A), that curve may then be taken, by its inverse form, to indicate the degree of rehance to be placed on the watch; in other words, the less irregular the curve which is called by the name of the watch not involved, the less valuable will be the indications of that watch. With a view to diagrams on this plan, the most convenient form of the chronometer journal is as follows:—

Date	_ A	A B	Dady	В	ВС	Daily Doff	C A SÃ
Aug t 1, 2 1, 3 1, 4 etc.	A PM A 10 5 0 9 47 0 10 13 30 9 54 0		6 5 9	m 1 54 30 5 36 24 2 47 5 43 31 5	0 14	s h. m 9541 20 9361 15 to 3 2 20 9423	32 10 58 8

This is the commencement of the journal represented in diagram No. 2. One division of the ordinates is equal to is. In this diagram we notice that the curve ((') has very small fluctuation from the borizontal, while (A) and (B), before a third of the month is over, begin to depart from regularity, and by the end of the month are very divergent. Now as the watch C is involved in each of these

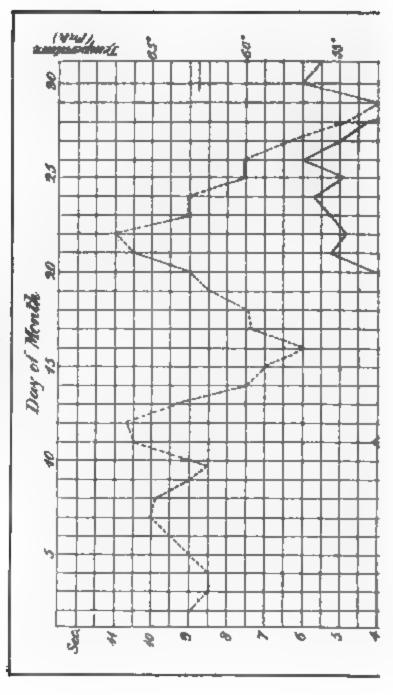

.

.

CHRONOMETER DIAGRAM Nº3.

H.M.S. Holspur", Mediterranean December, 1876. RELATIVE RATE CURVES

.

curves (A) and (B), we, with great probability, put that watch down as the offender, which is indicated also, at once, by the curve (C) being very regular. Diagrams formed on this plan do not, however, seem to be so well suited for exhibiting, side by aide, the curves of absolute rates with those of relative rates, nor for connecting the fluctuations of the rate curves with the disturbing influences. And one feature, which renders diagrams so valuable, we must always bear in mind; it is the facility with which the disturbing influences may be depicted, thus furnishing means of assigning each irregularity in the rate curves to its proper cause. When there are three watches on board, this method has the advantage of simplicity, but with a larger number, the work of getting out the differences renders it inconvenient.

In diagram No. 2, the curves on this from (A), (B), (C) are given for the three chronometers of H.M.S. "Flying Fish" during the month of August, 1874. The curves drawn on the second method, which follows, are given on the same sheet. The commencement of the chronometer journal is also inserted. We are indebted for this example to Mr. R. W. M.ddleton, navigating officer.

## (2) Second Method.

The axis of x represents the going of an imaginary mean watch, and the daily differences of the differences between this mean watch and the chronometer give the ordinates of the rate curves of the different chronometers. The chronometer journal may be conveniently tabulated as follows:—We take the same example, and place the curves A. B. C. on the same diagram; but here each division on the axis of y represents half a second instead of one second as before

1874	August 1st.	2nd.	3rd.	4th.	etc.
A B C	h. m. s. 10 5 0 9 54 30'5 9 54 18'5	h. m. s. 9 47 ° 9 36 24 9 36 10	h. m. s. 10 13 30 10 2 47'5 10 2 32	h. m. s, 9 54 0 9 43 11'5 9 42 54	
1	29 53 49	28 59 34	30 18 49 5	29 20 5'5	
M	9 57 56.3	9 39 21,3	10 6 16.2	9 46 41.8	
a ða	+ 7 3'7	+ 7 8.7	+ 7 13'5 + 4'8	+ 7 18's + 4'7	
δδ	— 3 25·8	- 3 27°3	- 3 29 - 1.7	- 3 30,3	
$\delta_c$	<b>—</b> 3 37·8	- 3 41°3 - 3°5	- 3 44°5 - 3°2	- 3 47 <sup>8</sup> - 3 <sup>3</sup>	

Where a=A-M, b=B-M, c=C-M, and  $\delta a$ ,  $\delta b$ ,  $\delta c$  are the daily variation of these differences. These latter are the quantities embodied in the curves. Checks in the calculation are afforded by the conditions a+b+c=0, and  $\delta a+\delta b+\delta c=0$ .

Diagram No. 3 gives the rate curves of the three chronometers of H.M.S. "Hotspur," Mediterranean, for the month of December, 1876, Mr. F. K. Taylor, navigating officer. During the whole of the month, with the exception of four days, the ship was at anchor, and the fluctuations will probably be all due to changes of temperature. In the example, diagram No. 2, motion is a considerable factor.

Chronometric Difference.—A term proposed instead of Meridian Distance, which see.

Circles of the Sphere.—If we conceive the sphere to be generated by the revolution of a circle about one of its diameters as axis, then the "circles of the sphere" may be defined as those circles

which are described on its surface by the extremities of such chords of the generating circle as are at right angles to the axis. The two extremities of the axis are considered to be the "poles" of each circle in such a system. Any diameter of the generating circle may be made the axis. Or we may regard the circles of the sphere as originating from the section of its surface by a plane.

Circles, Great.—Great Circles of the Sphere are those whose planes pass through the centre of the sphere, and which are therefore equally distant from both their poles, dividing the sphere into two equal parts. Distinguished from Small or Lesser Circles,

Circles, Small or Lesser.—Small or Lesser Circles of the sphere are those whose planes do not pass through the centre of the sphere, and which are therefore unequally distant from their two poles, dividing the sphere into two unequal parts. Distinguished from Great Circles.

Circles, Primary and Secondary.—The position of all points on the sphere may be defined by a system of co-ordinates, the size of which are a definite great circle and a system of great circles perpendicular to it; the former is called the Primary Great Circle, the latter its Secondary Great Circles. -See Co-ordinates for the Surface of a Sphere.

Circles of Altitude, Declination, Latitude —In the different systems of co-ordinates for the surface of the celestial sphere, it is the common practice to regard the secondary great circles as ordinate circles to the primitive, and they are hence named after that one of the co-ordinates which is measured upon them. Thus, the great circles which are ordinate circles to the horizon are called Circles of Altitude, because altitudes are measured upon them; the

great circles which are ordinate circles to the equinoctial are called Circles of Declination, because declinations are measured upon them; and the great circles which are ordinate circles to the ecliptic are called Circles of Latitude, because latitudes are measured upon them. Under a differenent system of nomenclature these are severally called Circles of Azimuth, Circles of Right Ascension, and Circles of Longitude.—See Co-ordinates for the Surface of a Sphere.

Circles of Azimuth, Right Ascension, Longitude.— In the different systems of co-ordinates for the surface of the celestial sphere, some writers allow the conception of polar co-ordinates to predominate, and thus regard the secondary great circles as sweeping out angles at the pole; they therefore name them after that one of the co-ordinates which is marked out by them. Thus the great circles passing through the poles of the horizon are called Circles of Azimuth, because they each mark out all points which have the same . azimuth; the great circles passing through the poles of the equinoctial are called Circles of Right Ascension, because they each mark out all points which have the same right ascension; and the great circles passing through the poles of the ecliptic are called Circles of Longitude, because they each mark out all points which have the same longitude. Under a different system of nomenclature these are severally called Circles of Altitude, Circles of Declination, Circles of Latitude.—See Co-ordinates for the Surface of a Sphere.

Circles, Vertical—or simply "Verticals."—Great circles of the celestial sphere, passing through the "vertex" of the heavens; they are perpendicular to the horizon. Also called "Circles of Altitude," and "Circles of Azimuth.'

Circles, Hour. Great circles of the celestial sphere perpendicular to the equinoctial, and therefore passing through the poles of the neavens. They severally mark out all points which have the same hour-angle -See Co-ordinates for the Surface of a Sphere.

Circle, Diurnal (L. diurnus, "pertaining to a day, from dies, "a day"). —The diurnal circle of a heavenly body is the circle it describes owing to the apparent daily revolution of the celestial concave. If the declination remains unchanged, the diarnal circle is coincident with the parallel of declination passing through the body. Only when the body is in the equinoctial is it a great circle. At the equinoces the sun's diarnal circle is nearly coincident with the equinocetial; at the summer and winter solstices, its diarnal circles in the heavens correspond nearly to the tropics of Cancer and Capricorn on the surface of the earth.

Circle of Perpetual Apparition. That parallel of circlenation beyon i which all the diurnal circles lie wholly above the horizon. Its polar distance is equal to the latitude of the observer's station.

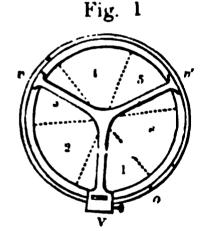

Circle of Perpetual Occultation -That parallel of declination beyond which all the diarnal circles he wholly below the horizon. It is at the same distance from the depressed pole as the Circle of Perpetual Apparation is from the elevated pole.

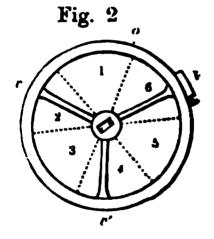

Circle of Illumination.—Approximately one-half of the earth's surface is always illuminated by the sun, while the opposite bemisphere is in the shade. The great circle which at any instant is the boundary between the illuminated and darkened hemisphere is miled the Circle of Illumination.—See Illumination.

Circles, Polar—The Arctic and Antarctic Circles.—Small circles of the terrestrial sphere, parallel to the equator, at the same distance from the north and south poles as the tropics are from the equator. This distance is about 23° 27'; these circles are therefore parallels of latitude of about 66° 33' N. and S.; "about," because their position is subject to slight periodical change.

Circle of Curvature.—The circle whose curvature is the same as that of the curve under consideration, at any given point.—See Curvature.

Circle, Troughton's Reflecting. A very elegant instrument, which is the same in principle as the sextant, and applied to the same uses. The accompanying figures will illustrate our brief notice of its peculiarities. The essential requisite in the construction of all reflecting astronomical instruments is, that lines from the

place of the eye and from the movable reflector at the centre of the arc to the fixed reflector, should make equal angles therewith. In the reflecting circle, the graduated limb consists of a complete circle, which is equivalent to six sextants, the adjuncts of the instrument and manner of observing bringing each of these sextants into play. There are three verniers (V, v, v'), the triple bar which carries them

leng of course connected and moving with the index glass of how vermers V) is furnished with the climp and langest serew for regulating the contacts, and when the reflectors are parallel this Last stands at or near 0. A complete observation with this But ment requires that the angle shall be taken derectly an inverse to To duce observation (fig. 1) of the angle is made, as with the Malar, by pashing the index forward along the limb. The degree, matte, and second is now read off by that vernier to what the war werew is attached (V); also the minutes and seconds sl. wa by as other two vermers (1, e). The angle is thus measure ton the different sextants. The reverse observation , fig 2 of the Magle at made by moving the index back along the limb to alout the men distance from the O as it was before moved forward, I ich was ng the instrument by turning it half a revolution round the he if vision, and finally making a perfect contact of the images with the sid of the tangent screw. The central reflector will now be med from its mittal position, parallel to the fixed reflector to the me extent but in the opposite direction, to what it was in the observation. The three vermers are then read off as before, ad thus the angle is measured on the three remaining sextants of he mrele

The mean of all six readings-off is the true apparent angle, responding to the mean of the two times at which the direct and rerse observations were made

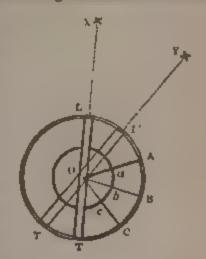

The advantages of this instrument, as compared with the sextant, these. By observing directly and reversely, all observitions for any the index error are rendered unnecessary, for if the universely of divisions be erroneous one way when the index is

pushed forwards, it will be so far wrong in the other direction when the index is pashed backward, diminishing or increasing the angle read off in the one case as much as it increases or diminishes it in the other. Again, the errors resulting from want of parallelism in the surfaces of the dark glasses are eliminated. When the matrament is reversed the direction of their inclimation is changed, and consequently the effect on the angle measured will be of a contrary kind in if it increased the angle before, it will now diminish it, by the same amount, and rice versa. The mean of the two sets of readings off will therefore be the true apparent angle, independent of index-error and error for imperiect shades Thus, also, the errors of the horizon-glass are entirely corrected, and those of the index glass very nearly. By having the three vermers to read off from different parts of the arc of the circle. any error resulting from imperfect centering is altogether corrected. If a single bar carried the index, and revolved upon an axis not exactly at the centre of the graduated circle, the angle indicated would be too large or too small, but if it is too large at one part of the circle, it will be too small at the opposite. Such errors are therefore, eliminated by having the triple index bar. By taking the me in cf the two sets of three readings each, errors arising from want of exactness in the graduation of the limb, or from the effects of warping, or any slight errors in reading off which do not compensate each other, are reduced to one-sixth of their simple value. The errele also has an advantage over the sextant in furnishing the means The adjustments of the two instruments of measuring a larger angle are of the same unture .- See Sextant.

Circle, Repeating.—A circle for measuring angular distances, constructed upon a beautiful principle invented by Borda. As absolute perfection in graduating an are cannot be attained, arrow

resulting therefrom are by this means indefinitely diminished, at least in theory. A brief description of "the principle of repetition" will explain the distinguishing characteristic of the instrument. O is the common axis of two circles ABC and abc. The larger circle ABC has its limb graduated, and is placed in the plane passing through the two objects whose angular distance is to be measured; let these (supposed fixed) be X and Y. The smaller circle abc carries the telescope TL, which is fixed to it, revolving on the axis O. A bar O A carries the vern or which reads off the graduations of ABC;

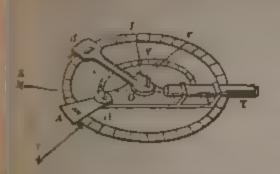

it is furnished with two clamps, by which it can be alternately attached to either circle and detached from the other. Let the telescope be directed to X, then read off. Clamp the index arm OA to abc, inclamping it from ABC, and carry the telescope round to the other object Y. The index arm, being clamped to abc, is thus carried over an arc AB, which measures the angular distance (XOY) of X and Y. Let it be clamped to

ABC If we now read off, the difference of the two readings obtained would give the angular distance required, but affected by the errors arising from imperfect graduation, which it is the express object of the repeating tircle practically to get rid of. Instead, then, of reading off the are AB, the index-arm, being clamped to ABC, is unclamped from abr, and then the telescope is moved back to the object X, leaving the index at B. The index-arm is now clamped to abr, and unclamped from ABC, and the telescope again directed to

the second object Y, carrying forward the index arm to C index will now have repeated the arc AB, and the whole, AC, if read off, would be twice the angular distance of X and Y. The process may be repeated any number of times (for example, ten), and the final are read off will be that number of times the angle XOY This reading will be affected by an error due to imperfection in graduation depending on two readings off alone, those corresponding to the initial and final position of the index; and in dividing the whole are by the number of times AB is repeated (e.g. ten), this constant error of graduation is divided to the same extent. Thus, in the example, the measurement of XOY maffected with only one tenth of the constant error of graduation. One great convenience of this instrument is that, in effect, the mean of a number of observations of an angle is obtained without the tediousness of multiplied readings-off. Again, " errors of observation " virtually disappear from the result, for these, when numerous, tend to balance and destroy each other. Some inknown obstacle, however, prevents any practical realization of the abstract advantage offered by the principle of repetition.

Circle, Borda's Repeating Reflecting. In this instrument the measure of an angular distance is taken by reflection, as in the sample reflecting circle; also the "cross-observation," as it is called, is the same in principle as the pair of observations taken directly and reversely. The principle of repetition is made available by using the index-glass and horizon-glass alternately as the fixed nirror. The index glass, at centre O, as in sextant) carries the index arm and vermer I. The horizon-glass H, and the telescope T, revolve together round the centre with the vermer 4. To the bar which carries these is attached also an inner circular are F, divided to degrees, called the "binder," as it enables us to set the mirrors to

any given inclination, and thus at once to bring two objects into contact roughly. The divisions of the finder are reckoned in both directions from the 0; and when the vernier I is set to this 0, the index glass and horizon glass.

parallel. The telescope bar can be clamped at pleasure to the 22 so also the index bar may be clamped either to the circle or the finder. Let the angular distance between X and Y be required. When the index bar stands at I, the angle pO I measures this distance, If the instrument be "reversed," and a contact then made, the index har will have moved through the position of parallelism Op to Or, the angle por being equal to pod, and dor equals twice the angular blance of X and Y. Let the instrument be now restored to its immand position. Leaving the index bar clamped to the circle being meamped from the anders, move the horizon-bar through the same legle a(b) and in the same direction as the index bar travelied; a wigh contact of the two objects will be thus again made, which Postset is perfected by the tangent-screw on the horizon vernier. Breything is now exactly as it was at starting, except that the two timers are transferred to other points of the circle, distart from Bur original positions by twice the angle measured. The operation by thence be repeated any number of times

The theoretical advantages of this instrument in eliminating or minishing errors will be understood from the two preceding rateles.

Circummeridian (L. circum, "about") -About or near the meridian Circummeridian altitudes are a set of altitudes of a body taken when it is in the vicinity of the meridian —See under Altitude.

Cirro-cumulus. One of the intermediate modifications of cloud. See Cloud.

Cirro-stratus. --One of the intermediate modifications of cloud. See Cloud.

Cirrus (L. "a lock of curled hair"). - The "Curl-cloud;" one of the primary modifications of cloud. - See Cloud.

Civil (L. ciedis, "relating to the community of citizens").—The civil time, year, day, is that reckning which is adopted for the social purposes of life. See Calendar.

"Clearing the Distance."—In finding the longitude by a "lunar distance," the operation of deducing the true from the apparent distance is technically called "clearing the distance." For the methods of doing this see under Longitude, Lunar Distances.

Olinometer Ship. An instrument for measuring the angle through which a ship heels.

- 1 The supplest form is a *Pendulum* attached to an athwartship bulkhead, with an accompanying are to indicate its departure from the vertical.
- 2 A better and equally simple contrivance consists of a pair of Relang Batters; these are graduated perpendiculars placed at the extremities of the bridge, whence the horizon is visible

- 3. Nollotte a Ship-Clinometer is a simple instrument formed on the principle of a carpenter's rule; applicable in a heavy sea, when the pendulum is useless
- 4 Short's Patent Shop-Clinometer is an instrument consisting of a tubular are of glass, iron, and vulcamte, partly filled with mercury. The top of the column of mercury, visible in the glass portion, rises or falls as the ship rolls, and indicates, against a scale boldly graduated to 1, the real angle of the roll of the ship. An electric apparatus is added, by which a signal from a bell is given when the ship reaches a dangerous roll.

[Sec "Journal" of the Royal United Service Institution, vol. savi, No. exiv, 1882 Also vol. xv, No. lxn, 1871.]

Clocks and Watches. - Navigation is vitally concerned with the machines by which time is measured. Every scientific navigator anould understand generally the principle and construction of the extronomical clock in the shore observatory, and of the chronometer on board his ship.

Moving Power. (2) the Converting Mechanism, (3) the Regulating Agency. (1) The moving power in astronomical clocks consists of a heavy weight, which descends by the force of gravity, the cord which suspends it passing over and giving a rotatory motion to a horizontal axle. The moving power in chronometers consists of a graing which is could up within a barrel, and unwinds itself by the force of its own elasticity—(2) The converting mechanism in both clocks and watches is formed of a series of wheels and panions small wheels furnished with what are called leaves, working in the mass of larger opposing wheels. By this train a rotatory motion may

be obtained, having any required ratio to that of the primary axle.

(3) The regulating agency in astronomical clocks consists of a pendulum, the oscillations of pendulums of uniform length being isochronous, or performed in equal times. The regulator in chronometers consists of a balance, making isochronous vibrations.

The contrivances by which these essential parts are articulated together constitute an important element in the construction of timekeepers. The energy of the moving power has to be periodically renewed by "winding up," which raises the weight or coils the By the manner in which the moving power is connected with the commencement of the wheel-work this process can be effected without arresting the motion of the other parts of the machine. In watches a Maintaining Power, consisting of a second spring, has to be introduced at this point. At the other end of the converting mechanism is the regulating agency, and these two are combined by what is called the Escapement. Unless restrained, the descending weight of the clock would acquire an accelerated motion and rapidly run down, and similarly, the spring of the watch would The escapement provides the necessary at once uncoil itself. checking influence, by bringing the alternating action of an oscillating body (the pendulum, or balance) and the rotary motion of the wheelwork to act and react upon each other. The pendulum acts, not only as the regulating agency, but contributes to the moving power by the action of gravity; the balance derives its motion entirely by its being transmitted to it from the spring. Both pendulums and balances are constructed so as automatically to compensate the disturbing effects of changes of temperature. A uniform motion is thus sustained and communicated by the wheel-work to the hands which indicate, on the dial, the lapse of time.

Clock, Astronomical. A pendulum clock, of very superior construction, and specially adapted for astronomical observations. It is an indispensable piece of furniture in every observatory [A abort and clear description of observatory instruments is given in "A Treatise on Astronomy, by Hugh Godfray (Macmillan & Co ) } The chief cause of irregularity in the going of clocks is the expansion and contraction of the pendalum from changes of temperature Compensating pendulams, such as the gridison of Harrison, or mercurial of Graham, as now constructed, secure an isochronous motion-ir. a perfect equality in the duration of the oscillations. important point in the mechanism is the "escapement," which sustains the motion of the pendulum and records its vibrations; and here also great perfection has been attained. Huyghens first adopted the pendulum, and to him also is due a simple means of winding up the clock without interfering with its regular and uniform progress. In the astronomical clock the second's tick is very distinct, that while the eye of the observer is engaged at the telescope, the ear may note the time. It is adjusted to show sidered time, and cating 0 0000 when the first point of Arics is on the meridian of the station, and going twenty-four hours between two successive transits of that point. The astronomer sets and regulates his sidereal clock by observing with the transit instrument the meridian passages of the more conspicuous and well known stars. Each of these holds in the heavens a known place with respect to the first point of Aires. and by noting the times of their passage in succession, he knows when the first point of Aries passed. At that moment his clock puglit to have indicated 0h 00 00; if it did not, he knows and can correct its error. Again, by the agreement or disagreen ent of the errors given by each star, he can ascertain whether his clock is

correctly regulated to go twenty-four hours in one diurnal period; and if not, he can ascertain and allow for its rate. Hence, by applying the error at a definite date, and the accumulation of the rate since, to the indication of the clock, the exact sidereal time proper to the locality of the station can always be obtained. The astronomical clock is of the greatest importance to the navigator, as furnishing a ready means of obtaining, by comparison, the error and rate of his chronometer.

Clock, Mean Solar.—A clock which indicates mean solar or civil time, and is therefore adjusted to twenty-four hours during the average length of the day, or one complete diurnal revolution of the mean sun in the heavens. The ratio which the duration of the mean solar day bears to that of the sidereal day is 1.00273791 to 1; hence it will be found that the twenty-fours of the mean solar clock corresponds to 24h 3m 56.55s of the sidereal clock.—See Day.

Clock, Sidereal.—A clock which indicates sidereal time.—See Clock, Astronomical.

Cloud.—A mass of visible vapour floating in the atmosphere. The classification of clouds and nomenclature introduced by Mr. Luke Howard is the system universally adopted, though later meteorologists have suggested modifications and amplifications. Howard defines and describes the three simple and distinct modifications of cloud, which he names "Cirrus" (ci.) "Cumulus" (cu.), and "Stratus" (s.); then two intermediate modifications, the "Cirrocumulus" (ci-cu.), and "Cirro-stratus" (ci-s.) with two compound modifications, the "Cumulo-stratus" (cu-s.), and the "Cumulo-cirrostratus," or "Nimbus' (n.). We have placed in parentheses the notation adopted to register each variety.

## Simple Modifications.

- 1 Corrus (L. "a lock of corled hair," from (ik, sipas, "a horn").

  "Curl cloud" Clouds of fibrous structure. Of all the modifications, they have the least density of aggregation, the greatest elevation, and most variety of extent and direction. They are the earliest to appear after serone weather, as a few white threads pencilled on the aky. These are reinforced by parallel flexuous or diverging streaks or branches, the upward direction of the tufts indicating condensation proceeding rain, their downward direction, evaporation and fine weather. Among seamen the cirri are known as "mare's tails," and are regarded as the precursor of windy weather. From their great elevation, the particles are probably frozen, and therefore crystalline; and hence, from reflection and refraction, the appearance of halos and similar phenomena, which are only observed in the cirris and its derivative forms, especially in the cirro-stratus. The halo commonly prognosticates foul weather.
- 2. Cumulus (L. "a heap," from Gk \*\*\*cua, "anything swollen")—
  "Heap cloud" though of a hilly structure. The lower surface is norizontal, the upper consists of conical or hemispherical heaps. Of all the modifications they are the densest, and are generally found in the lower regions of the atmosphere. The cumulus of fine weather has a moderate elevation and extent, and a well defined rounded surface. Trevious to rain it increases more rapidly, appears at a lower level, and with its surface full of loose fleeces and protuberances.
- 3. Stratus (L. "laid flat") -" Flat-cloud." Clouds consisting of an extended, continuous, horizontal sheet, increasing from below. Of the three primary modifications, the stratus is intermediate in density; in position it is the lowest of clouds, its inferior surface.

generally resting on the earth or water. As the cumulus belongs to the day, so the stratus is the cloud of night. It is dissipated by the return of the sun and morning breeze, when fair and serene weather is ushered in

## Intermediate Modifications.

The cirrus, after continuing for some time stationary or increasing, usually passes, while at the same time it descends to a lower position in the atmosphere, into one of the two following forms:—

- 1 Curo-cumulus.—Small, roundish, well-defined masses, in close horizontal arrangement or contact, formed by the fibres of the circus collapsing, as it were. This beautiful aspect of the sky is frequent in summer. It is the "mackerel back sky" of warm and dry weather.
- 2 Curro stratus.—Horizontally or slightly inclined masses, resulting from the subsidence, as it were, of the fibres of the cirrus. This cloud presents generally the character of the stratus in its main body, of the cirrus in its margin. When soon from a distance, it frequently gives the idea of shoals of fish. It precedes wind and rain, and is almost always seen in the intervals of storms.

## Combined Modifications.

1. Cumulo-strains. The modification of the cumulus, when the columns of rising vapour which go to form it arrive in the upper region, not satherently dry to round off its summits by rapid evaporation, allowing them to spread horizontally, and form flat-topped mushroom-shaped masses. Its tendency is to spread, overcast the sky, and settle down into the nimbus.

2 (umula-cirro-stratus or Nimbus (L. the ram-cloud) —A cloud or Teem of clouds from which rain is falling. It consists of a horizontal beet, above which the cirrus spreads, while the cumulus enters it terally and from beneath.

In Admiral Fitzroy's system there are four primary classes of clouds:—1 Cirrus; 2. Stratus; 3. Nimbus; 4. Cumulus. He adopts the principle of combining these words to describe the intermediate modifications, and renders the terms more explanatory of the precise and of cloud by the use of the augmentative termination onus and the diminutive ites—e.g. cirronus, cirritus, cirrono-stratus, cirrito-stratus, etc.

Co.—A prefix, being an abbreviation of Complement. Thus we have co-altitude, co-declination, co-latitude, co-sine, co-tangent, co-secant—See Complement.

Co-altitude. - The Complement of the altitude, called also the "Zenith distance" z=90°-a. When the body is below the horizon, a is negative, and the co-altitude exceeds 90°.

**Co-declination.**—The complement of the declination, called the "Polar distance."  $p=90^{\circ}$   $\delta$ ;  $\delta$  being considered negative when the declination is of a different name from the elevated pole.

Co-latitude.—The complement of the latitude.  $c=90^{\circ}$  l. In very many of the problems of celo-navigation a spherical triangle has to be solved, whose sides are respectively equal to p the polar distance of the heavenly body observed, z its zenith distance, and c the co-latitude of the observer. It must, however, never be longetten that this being a triangle of the celestial concave, c in this case is actually the polar distance of the observer's zenith. The co-latitude of the observer is the corresponding are of the terrestrial

Coefficients.—In algebra, the factors whose product constitutes a term are called coefficients of each other. But in expressions whose terms involve constant as well as variable factors, the word coefficient is usually restricted to the former, while the latter are distinguished as facients, In formulæ embodying physical properties, these coefficients are determined by experiment. The coefficient of friction for any substance is a familiar instance. There is another example familiar to the navigator. The magnetic condition of each individual iron ship is expressed by an algebraical formula, the terms of which involve the coefficients A, B, C, D, E; these represent the components of the constituent parts of the ship's magnetism, and are determined by experiment.

Collimation, Axis or Line of (L. collimare, form of collinere, "to level in a right line;" from con, "together," and linea, "a line"). The optical axis of the telescope, or the line joining the the centre and focus of the object-glass. One of the adjustments of the sextant and similar instruments is to render the axis of collimation parallel to the plane of the arc.

Columba (L. "The Dove").—A constellation next to, and to the S.W. of Canis Major. a Columba may be found by producing the line joining Procyon and Sirius to about the same distance. Mag. 2.7 N.A 1896; R.A., 5h 36m, Dec. – 34° 8′

Colures (Gr. κόλουρος, "cutting the tail;" from κολούειν, "to cut," and οὐρὰ, "the tail"). A term originally applied to any great circle passing through the poles of the heavens. It is derived, by some, from the fact that one part of each of these circles appears always "cut off" by the horizon. A more probable explanation of the word seems to be "cutting the tail" of the northern constellation.

Passing through the pole star. This star is situated in the tail of the Lesser Bear, a group which appears to have been more anciently figured as a dog; hence the pole star is call Cynosure integrape, "The Dog's Tail," κόων, κικός, "a dog," and οὐρα, "the tail, The word columns has more lately become restricted to the two circles of the system which pass through the four cardinal points of the schiptic—the equinoctial and solstitial points—the former being called the Equinoctial Column, and the latter the Nolstitial Column. The equinoctial column may be regarded as the initial position of the hour circle [Co-ordinates for the Surface of a Sphere]; the iolitical column passes through the poles of the ecliptic as well as those of the equinoctial. Even in the modern restricted sense this lead in now but little used

Commensurable (L. commensus, "the size of a thing in proportion to another"). Quantities are said to be commensurable then they can be expressed as an exact multiple of a common findamental unit: thus a quarter of an inch, an inch and a foot, are sommersurable. Opposed to Incommensurable.

Compass.—The compass is simply an instrument which utilizes be directive power of the magnet; its forms are various, according to the nace it is intended to serve. Its applicability for the purposes if navigation seems to have been recognized in Eastern Asia long more seamen in Europe knew its value. It was adopted in the fediterranean about the thirteenth century. The compass fitted nace on board ship is called "The Mariner's Compass," and, cording to the purposes it is specially adapted for, it is named the Steering Compass, The Standard Compass, and the Azimuth Compass.

Compass, Binnacle or Steering. - The "needle" or magnetized bar of steel, or a system of such bars, is attached to the under side of the circular card which represents the horizon, and which is graduated with the rhumbs of the horizon or points of the compass, the north end or "pole" of the needle being fixed under the north point of the card. This needle and card) is then balanced on a fine point which rises from the bottom of a brass bowl, protected by a covering of glass. The howl, properly weighted, is hung in "gnabals," so as to retain a horizontal position curing the rolling and pitching of the ship; on the inside of it is a mark called " Lubber's Foint," and when the steering compass is properly placed in its position (the ship being upright), a line passing through the pivot and this point is fore-and-aft, or parallel to the keel of the slap. The "binnacle," adapted for protection, and furnished with suitable lamps, receives the whole. The binnacle in some compasses is also furnished with a system of con pensators or "correctors" for reducing the deviations. Such instruments are those patented by Sir William Thomson and by Lieutenant Peichl, of the Imperial Austrian Navy. Ships have one or two permanently fixed binnacle compasses. In steering the ship, the object of the helmaman is to keep the keel in the direction of the course prescribed to him; to this end, as the compass card "travels" with the needle, that point, marked on the card, should be kept coincident with the lubber's point on the bowl. This, however, is only the general principle of steering. The binnacle compass is to be regarded solely as a guide to the helmsman, who has his directions given to him by the otheer of the watch. The officer has constantly to attend to the indications of the standard compass, which he translates into the corresponding directions for the helmsman at the steering compass,

Compass. Liquid, The oldest known form of the Marmer's Compass. As early as 2400 B.C., there is evidence that the Chinese were acquainted with the directive property of the loadstone, and utilized it for travelling; but tradition does not describe the details of the ancient instrument. First employed by the Vikings of Norway, about the ninth century of our era, the marmer's compass became protty generally known in Europe in the thirteenth century. A poem of that period tells us that a needle touched with the 'ugly brownish atone" was floated on water by a straw. [See Popular Lectures and Addresses Vol. III., By Sir William Thouson]. What was a necessary expedient before the discovery of the art of poising the needle on a pivot has been reverted to, in the present advanced state of science, in conjunction with the pivot, as the form best adapted for certain purposes.

The liquid compass is specially suitable for bout service where the swinging of the cards of other descriptions renders them useless; in particular, it is the only form that has answered in Torpedo boats and Torpedo boat Destroyers. Their construction obviates the effects of the severe vibration experienced at high rates of speed, and the peculiar 'scending motion of such boats in a seaway.

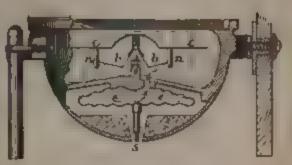

The characteristic feature is the substitution of a denser medium than air in the bowl in which the card acts. The liquid is a mixture of distilled water and pure spirit of wine, the spirit being added to guard against freezing. When arctic cold has to be encountered, undiluted spirit is used, in which case the card must be made of hard enamel. In ordinary cases a mixture of one part of spirit to two of water is employed. The compass bowl is completely filled with this liquid, in which the card moves freely. Two desiderates

are secured by this means. First—the pressure and consequent friction between cap and pivot is diminished and minimized by a boyant chamber or float below the central portion of the card: thus the instrument is rendered very sensitive to magnetic forces. Secondly—the friction of the liquid prevents the card being disturbed by the tremor in the vessel's hull when running at high speed with powerful engines or by the violent motion caused by a heavy sea. Under such circumstances steadiness is secured.

The bowl is so completely filled with the liquid, from which the air has been exhausted by means of an air pump, as to leave no air bubbles, and then accurately closed with screw-cap and washer. But the actual dimensions of the bowl and the volume of fluid it contains are constantly varying with every change of temperature and as these variations are different their relation to each other is altered. A compensating arrangement is therefore attached in the form of an elastic chamber of corrugated metal, like that of an aneroid barometer, into which any superfluity of liquid can pass from the main chamber, or a deficiency can be supplied through connecting tubes. It is very important to protect liquid compasses against the rays of the sun, especially in tropical climates, as excessive and rapid expansion of the liquid may involve breakage. When necessary the liquid may be withdrawn or replenished in the bowl through a filling hole appropriately fitted for the purpose.

In the liquid compasses constructed by Messrs. Dent, according to the plans and details drawn up by Captain Ettrick W. Creak, R.N., F.R.S., Superintendent of Compasses, Hydrographic Depart-

ment,—the Card cc is a mica disc and is supported on a point or pivot the actual bearing surface of which is a piece of native alloy of Iridium, the hardest metal known. The card is provided with a highly polished supplier cap hollowed out to maintain a central position on the pivot. The magnetic needles are enclosed in brass

cases hermetically sealed, n, n, and below the central portion of the card is the buoyant chamber, C This chamber, the needles and the cap, are permanently attached to the disc on which the cardinal and chumb points are painted, the whole collectively forming the complete "card." The point of suspension of this is above, and its centre of gravity below, the centre of flotation in the liquid contained in the logaid chamber Connected with this is the expansion chamber, e. the arrows showing one of the three passages by which the liquid papers into and out of the main chamber as the temperature changes. Beliew is the screw connexion, s, by which the expansion chamber is distended to the required extent when the howl needs refilling ; around this is lead ballast attached to the false bottom of the bowl. These standard liquid compasses for Torpedo boat destroyers are supplied with an azimuth circle, designed with a special view to taking bearings quickly in a rapidly moving vessel. The prism arrangement is also fitted so that the compass may be readily freed from the olacuring effects of spray and rain.

Compass, Standard.—(I.) That instrument on board ship which is recognized as the authority to which the indications of the other compasses are referred. Its position is carefully selected with a view to its being as free as possible from the disturbing influences of the ship's magnetism; it is adjusted and compensated, and the deviations are ascertained and recorded in a Table of Deviations; and the courses entered in the log are those which it would indicate.

- II.) In a naval service, by the Standard Compass is also understood the officially authorized compass, and we may refer to those in use in the navies of *England*, *France*, and *America*.
- 1. In 1837, the Lords Commissioners of the Admiralty appointed a committee of scientific and practical men to consider the subject of ships' compasses, and the instrument constructed by them is used as the standard in the navy. It answers the purpose of a steering compass and an azimuth compass.

The bowl is of stout copper with a view to calm the vibrations of the needle. and the intersecting point of the axes of its gimbals is made to coincide with the point of suspension of the card, and also with the centre of the azimuth circle. The bowl may be released from the ordinary gimbal suspension and hung in vulcanized indiarubber, in case of great oscillation arising from powerful engines.

The magnetic needles employed are compound bars, formed of laminæ of clock-spring steel, which is capable of receiving the greatest magnetic power. Each card is fitted with four needles, fixed

perpendicularly to, and equi-distant, on a light framework o brass screwed to the card; the pair of central needles are each 7.3 inches long and the pair of external ones each 5.3 inches; the extremities of the pairs of needles are respectively 15° and 45° from the extremities of the diameter of the card which is parallel to them. This arrangement renders the action of the card uniform; the needles being so arranged as to give equal moments of mortia for all diameters of the card when vibrated. Balancing slides are attached to adjust for alteration in dip.

The cond is formed of a mice plate, on which the paper is cemented before the impression of the rhumbs is made, distortions from shrinking being thus prevented and a more perfect centering attained. Two cards, A and J, are supplied with each compass; the former being that in ordinary use, the latter being substituted for it in stormy weather, when the ship is subject to much motion. The whole weight of the lighter card A, with framework and needles, is 1525 grains.

Parats are furnished adapted for use with the two cards. For eard A, two pivot points are supplied tipped with "native alloy," which is harder than steel, and does not corrode by exposure to the atmosphere, and two spare pivots pointed with hardened steel, electrically gilded. The pivot-caps are of ruby or agate. For eard J, two pivot points are supplied which are ruby tipped; the pivot-cap is coated with speculiin metal. There is an apparatus at the saile of the bowl for lifting the card off the pivot to preserve it from injury when moving the compass or exercising heavy guas.

The magnetic axis of the needles points to the zero of the card; the various adjustments for centering, and the elimination of errors due to the displacement of sight-vanes and of prism, are all carefully made at the compass observatory at Deptford.

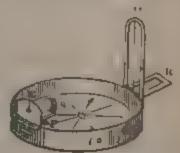

[See "Instructions for the Use of the Admiralty Standard Compass,"]

- 2. The standard compass in the United States Navy is Ritchie's Liquid Compass. This consists of a skeleton card mounted on a pivot, and having the bowl filled with a liquid composed of thirty-five parts of alcohol and sixty-five parts of distilled water, the freezing point of the mixture being 10° F. For arctic voyages pure spirit is used. The needles, two in number, consist each of six laminæ of "Stubb's Sheet," a steel of uniform excellence and high magnetic capacity. Each needle is 6½ inches long, and weighs a little less than two ounces. These needles are enclosed in two tubes placed parallel to the N. and S. line, and connected at their centres by a third tube; this last supports the cap upon which the card is pivoted. These tubes also serve as air-chambers and give great buoyancy to the card. One point of excellence in this compass is the very small amount of friction on the pivot.
- 3. In the French Navy the regulation compass is Duchemin's. The magnet consists of two eccentric circular magnetic rings with a diametrical bar connecting the poles. The maxima of the magnetization of the rings are at the N. and S. points, and the power diminishes gradually to zero at the E. and W. points. The card is a star, with eight points carrying a rim with the intermediate graduations. One good feature of this compass is the great fixity of the lines of its poles.

Compass, Aximuth.—A compass of very superior construction, specially fitted for taking bearings. On board ship it is mounted on a stand in a commanding position, so that an observer can sweep the horizon. Its characteristic feature is the employment of, a glass prism, the interior surface of one of the faces serving as a mirror in which is seen by reflection either the graduation of the card or the object observed, while the other is viewed directly, thus furnishing the means of reading off conveniently and accurately the azimuth of the object. Two arrangements for the purpose have been devised: (1) ring carrying vanes and prism: (2) tube carrying leus and prism. The former is the form of the old standard compass used for about 50 years in the Royal Navy; the latter is the plan invented by Sir William Thomson, whose compass was adopted in 1889 as the standard. A detailed description of those two instruments follows.

Compass with sight-vanes and prism. The night-vanes and prism are carried on the detached rim of the circular box containing the compass card with which it is concentric. This circle has an independent horizontal motion round its centre. The pair of eight vanes are fixed upon it with hinges diametrically opposite to each other. The "object-vane" (0) is an oblong frame having a fine

thread or wire stretched along its middle, by which the point to be observed is intersected. It is also furnished with a reflector (R), which by a hinge can be directed either below or above the horizontal plane passing through the observer's eye. This

shows his own level. The "eye-vane ' (E) consists of a plate having

a very narrow slit, which forms the sight through which vision is directed in taking an observation, the "line of sight" passing directly over the centre of the compass-card This slit is enlarged at its lower extremity into a circular hole, through which the graduations of the compass-card are read by reflection in a prism (P) attached to the vane. The plate in which this prism is fixed slides in a socket, and thus admits of being raised or lowered as required. Distinct vision of the graduation of the compass-card is thus obtained; and if the slit of the eye-vane be brought immediately over any division, that division, as thus seen by reflection, will appear to coincide with the thread of the object-vane, which is viewed directly. The eye-vane is furnished with set of dark glasses (S), to be used as shades when the sun is the object observed. The compass-card is very carefully and minutely graduated; besides the points and quarterpoints being marked, the circumference over which the prism passes is graduated in degrees. and usually cut to every twenty minutes; and this graduation is arranged so that we may read off the bearing at once, and is reckoned in more ways than one, for facilitating taking bearings from different cardinal points. The card can be brought to a rest by a stop (T) in the case, but this is not generally used in taking bearings at sea. The compass-card often has some motion on board ship, and the card may not be stopped exactly in the middle of its vibration, which is essential to a true result. Instead of using this mechanical contrivance to obtain accuracy in reading off, dependance is rather placed on celerity of observing; the mean of two or more observations taken quickly furnishes the most There is also a contrivance for throwing the card off reliable result. its centre when the instrument is not in use, to prevent the fine pivot being worn, and the sensibility of the instrument being impaired.

Compass, Lord Kelvin's (Sir William Thomson's).—
The compass is the instured outcome of the principles worked out by Sir G. B. Airy, the Astronomer Royal, in 1840, for the correction of compasses in iron ships. The following is abstracted from Lectures deticeral at the Royal United Service Institution on Feb. 4th, 1878, and May 10th, 1880 (See Journal Vol. XXII., No. 94, and Vol. XXIV., No. 106): and from Popular Lectures and Addresses Vol. III by Sir William Thomson. We shall arrange the description under the three headings: (1) The compass-card (including magnets and fittings) and its bowl: (2) The binnacle with the appliances for compensating the compass errors: (3) The Azimuth apparatus for taking bearings.

1. The Compass card (including magnets and fittings) and its bowl. The object being to obtain the greatest amount of steadiness of the compass at sea, and best adapt it for the perfect correction of the error due to the iron and cargo of the ship, the principles of its construction are stated to be-(1) For steadiness a very long vibrational period with small frictional error; (2) Short enough needles to allow the correction to be accurate on all courses of the thip for the place where the adjustment is made : (3) Small enough magnetic moment of the needles to allow the correction of the quadrantal error to remain accurate to whatever part of the world the ship may go " "The vibrational period" is the time the needle takes to perform a complete vibration to and fro, when deflected horizontally through any angle not exceeding 30° or 40°, and laft to stacif to vibrate freely. "The magnetic moment" is what is commonly called the "power" or "strength" of the needle. resulting instrument is thus described :

Eight small needles of thin steel wire, from 3½ to 2 inches long, weighing in all 54 grains, are fixed (like the steps of a rope-ladder) on two parallel silk threads, and slung from a light aluminium circular rim of 10 inches diameter by four silk threads through eyes in the four ends of the outer pair of needles. The aluminium is connected by thirty two stout silk threads, the

spokes as it were of the wheel, with an aluminium disc, about the size of a fourpenny-piece; forming the nave. A small inverted cup, with sapphire crown and aluminium sides and projecting lip, fits through a hole in this disc and supports it by the hp; the cup is borne by its supplier crown on a fine iridium point soldered to the top of a thin brass wire supported in a socket attached to the bottom of the compass bowl. The aluminium rim and thirty-two silk thread spokes form a circular platform which bears a light circle of paper constituting the compass card proper. For the sake of lightness a circle of 6 inches diameter is cut away from the middle of the paper, leaving an annular band, 2 mohes broad, on which are engraved the points of the compass and a circle divided to degrees, The paper ring is out across in thirty two places, inidway between the silk thread spokes, to prevent it from warping the aluminium rum by the shrinkage it experiences when heated by the sun. The entire weight of the card (including run, needles, have, cap, paper

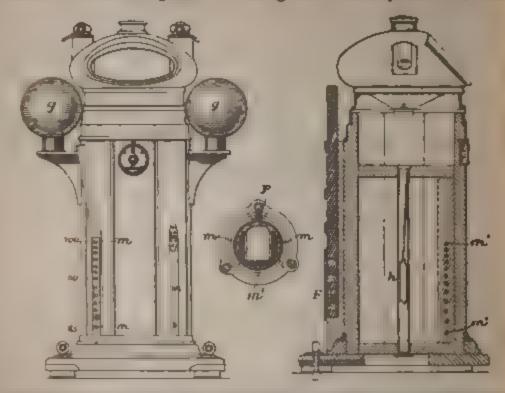

and threads) is about 170 grains, To obtain ateadiness of the Complement in vessels of war during gun-fire, and in steamers generally which there is great vibration, due to the working of the engines, wrew, and other causes, the suspension is by means of a brass spring reserribling a rope grummet, but with elastic brass wire instead of the rope The compass-bowl is suspended from the elastic ring with the intervention of a rigid gimbal ring. The elastic ring has two welkets fixed at the ends of a diameter, which rests on two balls attached to the brass rim of the binnacle stand. The elasticity of the ring mitigates the effect on the knife edges bearing the gimbal "The and bowl, and on the point bearing the compass-card, of vertical the thors of the platform on which the binnacle rests. Edges of the gumbal ring are supported on two grooved stirrups, hung b) chains from the elastic rings. This suspension initigates the effect of the horizontal tremors of the platform.

2 The Binnacle with appliances for correcting the company errors. The Hinnacle contains all the mechanical appliances for realizing in fractice the principles of correction discovered by Captain Flinders, in 1801, (Phil Trans, 1805, p. 187), and Sir George B. Airy, in 1837. The essential characteristic of the binnacle is not only that it contains within itself all the correctors, but that this is done in such a manner as to furnish the means for making, with case and certainty, the proper changes in the adjustment of the correcting magnets whenever observation shows change to be necessary.

The shortness of the compass needles and their small magnetic moment permit the complete correction of the quadrantal error.

This is done by a pair of unmagnetic iron globes, j.g., (solid or hollow) of the requisite size, which can by appropriate fittings be placed and

fixed once for all in proper positions on the binnacle, on the starboard and port sides of the compass, at equal distances from the centre of the card. When so placed no change for this adjustment is ever

necessary for the same ship and the same position of the compass in it, except in the case of some changes in the ship's from or iron cargo or ballast, sufficiently near the compass to sensibly alter the quadrantal error.

The part of the semicircular error which is caused by the subpermanent magnetism of the ship is corrected by bar-magnets in symmetrically placed long horizontal holes thwartship and fore and aft within the binnacle; and the part of the error arising from vertical induction in the iron of the ship by a Flinders has attached to the

binnacle outside on the fore or aft side. The corrector magnets provided for the 10 meh compass are round bars of glass-hard steel 9 inches long and '4 of an inch or '2 of an inch diameter. Each magnet painted blue in one half of its length and red in the other half, to mark the end possessing the same kind of magnetism as the earth's north and south polar regions. The fore and aft corrector holes, m, m, are in two vertical rows at equal distances of about 5 inches from the middle of the binnacle. The athwartship corrector holes, m', are in one vertical row about the same distance forward or aft from the centre of the binnacle. The holes in each vertical scale are spaced to give equal augmentation or diminution of corrective force, when one of the corrector-magnets is shifted up or down from hole to hole in order. These are marked with numbers proportional to the corresponding corrective force. A part of the semicircular error armses from the component of the ship a horizontal force on the compass which is due to magnetism indiced by the vertical component of the terrestrial magnetic force. This is corrected by what is called, after the inventor, a Flin lers bar, F. That which is supplied is a round bar of soft iron, 3 inches in diameter, and of whatever length of from 6 inches to 24 inches is found to be proper for the actual position of the compass of any particular slap. To make up the proper length it is supplied in pieces of 12 inches, 6 inches, 1, melies, and two pieces of for an inch. In making apthe proper length the longest piece should be appear out and the others below it in order of the r lengths. The weight of the har is supported on a wooden column or bar resting on a pedest a fixed to the bunnacle near its fiot, this wooden bur being cit to such a arigth, ar so made up of pieces as to give the proper height to the upper and of the iron bur. The compound column of iron and wood is kept.

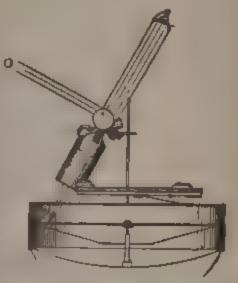

in position and protected from rain and spray by a brass tube with upper end closed, going down over it. The Flinders bar is placed in the fore-and-aft midships vertical plane, on the fore side of the binnacle when the north point of the compass is drawn towards the stern by the vertical soft iron, and in the middle of the aft side when the north point is drawn in the contrary direction.

The heeling error is corrected by three, two, or one bar-magnets in a brass can, h, hung by a chain, by which it can be moved up and down and secured in any position, in a brass tube fixed in the centre of the binnacle, under the compass bowl. The part of the heeling error which depends on magnetism transiently induced by the vertical component of the earth's magnetic force is always partially, and may be wholly corrected, by the globes and the Flinders bar. The heeling error on the east and west courses is wholly corrected by the Flinders bar.

described as follows.—"A tube, so placed that an observer looking down centrally through it sees the divisions on the compass card beneath, is supported on a frame resting on the cover of the bowl, and moveable round a vertical axis. In the tube is fixed a lens at such a distance from the compass-card that the degree divisions of its rim are in the principal focus. At the top of the tube a prismatic mirror is mounted on a horizontal axis, round which it can be turned into different positions when in use." The mirror covers about one half of the top of the tube, and may be turned on either the upper or lower half. The former is its position in the first and principal method of observing, in which the object is seen by reflection as in the camera-

lucida; the latter is its position when reversed for the second method of observing, in which the graduations of the card are read by reflection, as they are in the old azimuth compass with circle mounted prism. The prism-mirror is furnished with shades and balancing appendages.

When taking a bearing by the first method, the observer turns the instrument round its vertical axis until the 0 mirror and lens are fairly opposite to the object. He then looks through the lens at the degree divisions of the compass card, and turns the mirror round its horizontal axis till he brings the image of the object to fall upon the card; and thus is enabled to read directly on the card the compass bearing of the object. In the instru-

ment as constructed, the focal length of the lens is chosen to suit an altitude of 27° or thereabouts; but the error involved for bearings of sun or stars at altitudes of from 0° to 50° or 50° is practically immaterial.

The second method of observing is by looking direct at the object over the top of the prism, which is now kept turned (arrow head on thumb-screws down) with its mounting stopper against the frame work. As before the observer turns the instrument bodily round its vertical axis till the prism and lens are fairly opposite to the object. Then placing his eye so as to see the object over the prism, he reads

its bearing from the compass card, the degrees of which are seen reflected in the prism. This method is applicable to objects on the horizon, and is more particularly useful for taking bearings of distant landmarks which are too indistinct to be seen reflected in the prism.

The advantages of the instrument may be summed up as follows:

- 1.—Its use for taking bearings of objects even on the horizon is not interfered with by the globes constituting the quadrantal correctors, which are an impediment in taking bearings with the vanes and prism attached to the old horizontal-azimuth circle. It was to obviate this difficulty that the instrument was first conceived.
- 2.—It does not require any adjustment such as that by which in the vanes and prism compass the hair is brought to exactly cover the object. The only turning of the instrument round the vertical axis required in such as is necessary to bring the object into the field of view, which is sufficient to enable its image to be seen and the bearing to be read off on the divided circle of the compass card. This is a most important consideration in rough weather at sea, and when there are flying clouds which just allow a glimpse of the sun or star to be caught without allowing time to perform an accurate adjustment.
- 3.—Another advantage, particularly important in taking bearings at sea when there is much motion, is that it is not necessary to look through a small aperture as in the old vane fitted prismatic compass. The eye may be placed at any distance, of from one inch or two to two or three feet, from the compass, according to convenience, and in any position, and may be moved about freely through a considerable range on either side of the line of direct vision through the lens, without at all disturbing the accuracy of the observation.

This observation is rendered easy by the image of the star being thrown directly on the graduation of the card, which may be illuminated by a binnacle lamp to any required degree of brilliancy. A moderately bright star is seen as a fine point on a degree division, or between two, the intermediate distance being easily estimated to the tenth of a degree.

An accurate sun-azimuth may also be taken with the assistance of a shadow-pin, with which the instrument is fitted, when the sun is bright enough to give a good shadow on the compass card.

Compass-Card,—It is most important to understand clearly what the compass-card represents. It is balanced so as to be parallel with the plane of the horizon, and, by the power of the magnet which is fixed to it, it remains stationary, while the ship, which carries its pivot, revolves below it. It may be regarded then as identical with the horizon of the observer, and its graduated circumference indicates the points of division of the horizon. Radii of this circle were formerly called rhumb-lines (from a Greek word meaning a "whirl"), and they marked out the direction of a ship's course or the bearing of any object.

The circumference of the compass-card is divided according to two systems of notation into points or degrees.

1. By Points. —There are 32 points, each of which contains 11° 15'.

The names of the four principal, or, as they are called, the Cardinal

Points, are North (written N.,) South (S.), East (E.), and West (W.); the east being towards the right when the observer faces the north. The rest of the points are named by a combination of these four words. The four points (which may be called the Secondary Points) midway between the

several pairs of cardinal points, take their names from the pair between which each lies. They are the North-East (N E.), North-West (N.W.), South-East (S.E.), and South-West (S.W.). Again, the eight points (which may be called the Tertiary Points) mid-way between each cardinal and adjacent secondary point are named on the same principle, by compounding the names of the points between which each lies. Thus, the point half-way between N. and N E. is called North-North-East (N.N.E.); and so we have E.N.E., E.S E., S.S.E., S.S.W., W.S.W., W.N.W., N.N.W. The remaining sixteen points (which may be called the Subordinate Points, or By-points) are reckoned from the cardinal or secondary point to which each is adjacent, the name of which it takes qualified by the name of the succeeding cardinal point towards which it lies. Thusthe point next to N. towards E. is called North by East (N. b. E.). that next to N.E. towards the North is called North-East by North (N.E. b. N.); and so we have N.E b. E., E. b. N., E. b. S., S.E. b. E., S.E. b. S., S. b. E., S. b. W., S.W. b. S., S.W. b. W., W. b. S., W. S. N., N.W. S. W., N.W. b. N., N. S. W. The points of the

compass are frequently spoken of with reference to their position to the right or left of the cardinal point towards which the spectator is looking; thus N.N.E. is said to be "two points to the right of North;" W.N.W. "six points to the left of north." Each point is again sub-divided into half-points and quarter points, and these are named upon the same principle as the subordinate points. Thus the division half-way between E.N.E. and E. b. N. is called either East-North-East half East (E.N.E. & E.), or East by North half North (E. b. N. & N.) In choosing the name to use we must be guided by circumstances. In some problems it is convenient always to reckon uniformly from north or south, but generally the simpler name will be the preferable one, especially as these names are used in giving orders to the helmsman. And similarly for quarters and three quarters of a point.

2. By Degrees.—The whole circumference is divided into three hundred and sixty degrees (360°), each degree containing mixty minutes (60°), and each minute sixty seconds (60°); the limb being generally cut to twenty minutes. This furnishes a notation for the compass more minute than points, half-points, and quarter-points. We still reckon from the cardinal points; thus, to indicate a division which has 73° 54′ 30° to the east of north, we write N. 73° 54′ 30° E.

Compass-Card, Dumb.—A card without a needle, which can be substituted for the regular needle-attached card in an azimuth compass, or mounted on a special stand. It forms thus a simple azimuth instrument, independent of the magnet, its purpose being merely to determine the true bearing of the ship's head with reference to another object of which the true or correct magnetic azimuth is known. The practical way of proceeding is as follows:—(1) The true

Tables, the rim carrying the vanes is screwed to the dumb-card with its index on the graduation giving the true bearing of the heavenly body. This body being then brought on the line of sight at the time for which the calculation was made, the lubber's-point will indicate the reading on the card, giving the true azimuth of the ship's head. (2). Instead of a celestial body, a terrestrial object, whose correct magnetic bearing is known, may be used. When a ship is swung for deviation, the dumb-card is thus very convenient for bringing the ship's head on the correct magnetic bearings which are successively required. Instruments fitted with a dumb-card and known as a Bearing Plate, and Pelorus, which see.

Compass—I. Imperfections, II. Adjustments, III. Hrrors, of the Instrument.

- I. Imperfections, or essential defects, which should lead to the rejection of the instrument.
- 1. The pivot must be in the centre of the graduated circumference of the card.—To examine whether there is an imperfection in this point, observe the difference of bearing between two objects measured on different parts of the circumference. If there be no imperfection, this difference will be the same at whatever part of the arc it is measured.
- 2. The eye-vane and the object-vane must each be vertical.— Examine on shore whether they coincide throughout their length with the direction of the plumb-line.
- 3, 4.—There are two other imperfections, which, however, do not prevent correct results being obtained, if they are recognized as "errors"—which see.

II. Adjustment, where machinery is attached to the instrument, by which it may be put into order.

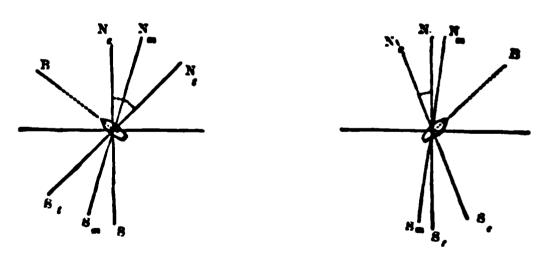

The needle with card must work on its pivot horizontally.—The "dip" causes the needle to deviate from the horizontal, and as the amount varies in different places, and also goes through cycles of change at the same place, the needle is formished with sliding weights, by the movement of which it may always be brought to the horizontal. A compass which is not furnished with these appliances may be adjusted by dropping sealing-wax on one end of the needle.

- III. Errors, acknowledged, and their effects allowed for or eliminated.
- 1. The direction of the magnetism of the needle, or the "magnetic axis." must be parallel to the longitudinal line of the needle, which then points with exactness to the magnetic north and south. To examine whether this is the case, place the needle with its reverse side on the card; the north point of the card, if there is no imperfection, will still point in the same direction as before, as indicated by a mark in the lining of the box. As this error obviously affects all points of the compass alike, it may be included in the total variation of the particular compass as found by observation, and therefore need not be made the subject of separate examination. It is acknowledged and allowed for, like the "index-error" of the sextant.
- 2. The line joining the eye-vane and the object-vane, called the "line of aght," must pass directly over the pivot. To test this, note excefully the bearing of a distant object, and then turn the compass ball round, so as to reverse the vane and the sht, repeating the operation with another object eight points from the first. The

bearings taken directly should be identical with those taken by reversion. The effects of this error may be eliminated by taking the mean of the direct and reversed bearing every time the instrument is used.

Compass Corrections.—The corrections of the compass are those angles which must be applied to the indications of the instrument to obtain the reading that would be given if the north point of the compass-card corresponded to the north point of the horizon. There are two principal corrections, variation and deviation. Variation is the disturbance caused by terrestrial magnetism, and varies with geographical position. Deviation is a further disturbance arising from the effect of magnetic influences in the ship itself which carries

Fig. 1. Fig. 2.

the compass. There is a third correction sometimes necessitated by disturbances arising from "local attraction" extraneous to the ship, and to which the unappropriated term "deflexion" might be specially applied. Omitting this last, the manner in which these corrections are applied will be best seen by drawing lines to represent the compass north and south line or meridian  $N_c$   $S_c$ , the magnetic meridian  $N_m$   $S_m$ , and the true meridian  $N_t$   $S_t$ . The variation is the

angle between N/ S/ and Nm Sm, and the deviation is the angle between Nm Sm and Nc Sc. To deduce the true from the compass course or bearing, No So (fig. 1) is first drawn; then, according as the deviation is east or west, Nor will be to the west or east of No. Again, No Sm being now drawn, No will be to the west or east of Nm, according as the variation is east or west. No No in the resulting entire correction to be applied. Thus if No B is a compass course or bearing, by applying No No the true course or bearing N, B is found. The entire correction is obtained directly at sea by amplitude and azimuth observations, and might, in its total form, be applied at once to the compass indications if an observation were made for every direction of the ship's head during the day. When it is required to deduce a compass course from a true course, the converse process to the above is pursued. No So (fig. 2) is first drawn; then, accordingly as the variation is east or west, Nm is to the east or west of Ne; again, Nm Sm being now drawn, Ne is to the east or west of Nm, according as the deviation meast or west.

Compass Compensations.—The mechanical modes of peutralizing or reducing large deviations of the compass by fixed magnets or masses of soft iron.—See Compass Deviation in Iron-built Ships.

Compass, Variation of.—The angle which the direction of the magnetic needle makes with the meridian. It is said to be Besterly when the north end of the needle is drawn to the eastward, and Westerly when it is drawn to the westward of the true north. The variation is different in different places. In any given place it goes through a cycle of change, becoming alternately east and west; it also changes slightly at different times of the day and periods of the year.

Variation is one of the "corrections" in deducing the true or bearing from the course and bearing observed with the course and bearing observed with the course are given on the charts used in navigation.

To determine the variation.—Compare the bearing of the other celestial body as shown by the compass with the true as found by observation and calculation. The difference of bearings will be the total deflection of the magnetic needle terrestrial variation and deviation which together form what the "compass error." If the observation is made with a on shore untiffuenced by local and ship attraction, the variationece obtained; when the observation is made on board ship, to obtain the variation as a separate result, the deviation known. The true bearing for the above purpose is obtained in the computation either of the Amplitude or Azimuth variation may likewise be obtained by comparing the tempass bearings of some terrestrial object.—See Bearing.

Compass, Deviation of.—The angle through which on board ship causes the compass-needle to be deflected to magnetic meridian. It is said to be Easterly when the north the needle is drawn to the eastward, and Westerly when it to the westward of the magnetic north.

Deviation is one of the "corrections" in deducing the treor bearing from the course and bearing observed with the co-It is determined before the ship leaves harbour, and a Table amount for every direction of the ship's head inserted in the the log-book. To do this requires the process called "Switche Ship," which see. When the deviation is large, it is compensated or reduced by the application of mechanical contrivances.

Compass Deviation, Constant, Semicircular, Quadrantal —In all vessels, whether built of wood or iron, the deviation consists of two principal constituent parts, the "Semicircular" and the "Quadrantal," with the occasional addition of a small "Constant" part. Each of these is in itself subject to regular laws, and any apparent irregularity arises from different combinations of the several parts.

1. Constant Deviation.—As far as this is a true deviation, it is small in amount and does not change with a change of latitude. It appears when the soft iron is not symmetrically arranged on each side of the fore-and sit midship section, or when the compass is not on the midship fore and all line. It arises from terrestrial induction. The coefficient of this part of the deviation is A.

An apparent constant deviation is introduced by index or other instrumental errors, or by errors in the assumed direction of the magnetic meridian.

2 Semicircular Deviation. —As the ship's head moves round a romplete circle in azimuth, this part of the deviation is easterly in one semicircle and westerly in the other. Lence its name. The "neutral points," or points where the semicircular deviation is zero, are opposite to one another—in wooden ships coinculing nearly with the magnetic incridian, and in iron ships being determined by the position of the ship while huilding. The semicircular deviation changes with a change in geographical position. This deviation is caused partly by sub-permanent magnetism, and partly by vertical induction in the iron of the ship. The horizontal part of this force

is resolved in two directions, one acting in the fore-and aft line of the ship ( + when drawing the marked end of the needle forward, when drawing it aft), and the other acting athwartships ( + when drawing the marked end of the needle to starboard, - when drawing it to port). The coefficients of the two parts are distinguished by the letters B and C.

3. Quadrantal Deviation.—As the ship's head moves round a complete circle in azimuth, this part of the deviation is alternately easterly and westerly in the four quadrants: honce its name. The "neutral points," or points where the quadrantal deviation is zero, coincide very nearly with the cardinal points. The quadrantal deviation remains unchanged in all magnetic latitudes. This deviation is caused by the transient magnetism of horizontal iron in the ship derived from terrestrial induction. This force is resolved in the same directions as the sub-permanent force. The coefficients for the quadrantal deviation are the letters D and E.

Compass, Heeling Disturbance of Deviation.—The compass on board ship is adjusted when she is on an even keel, the necessary compensations being made and the Table of Deviations drawn up under that condition. In iron-built ships, and also in those constructed of wood with iron beams, the deviation is greatly affected by the heeling of the ship, and the values recorded in the Table of Deviations are thus disturbed. An additional mechanical compensation may be introduced, or the requisite modification applied as a correction.

To understand the causes of this disturbance we must remember that it arises partly from the change in the action of the sub-permanent magnetism of the ship, and partly from a changed development of induced magnetism. (1) It is the horizontal powers of the ship's magnetism that affects the direction of the modile, and when a ship heels, forces which before acted vertically, and therefore did not disturb the horizontal needle, now act on one like, and produce deviation. (2) New forces develop in iron (such from decks), which, previously horizontal, becoming inclined, needly magnetism by induction from the earth's vertical magnetism.

The general law of the effect of heeling is thus given in Airy's billatons. When a ship's head is east or west, no sensible effect is produced by heeling. When the ship's head is north or south, heeling produces the greatest effect. Usually, but not in all cases, the marked, when the ship in north latitudes, and the unmarked, or south, end is north latitudes. Often in iron ships, with ship's head north or with, one degree of heel produces one degree of disturbance of the tempara, but in some instances one degree of heel produces two degrees of disturbance of the compass; in many of our men-of-war does not exceed half a degree.

Compass Deviation Formulæ.—The deviation may be presend in algebraical formulæ, the several terms of which represent a constituent parts arising from the different forces acting upon the appara, resolved in definite directions. Some of these formulæ are proximate, others exact. For each ship the coefficients are proximate, others exact. For each ship the coefficients are proximated by experiment, and then the formula gives the deviation any direction of the ship's head. The following summary is neverted from the "Admiralty Manual," which gives Poisson's neral theory, and Archibald Smith's investigations.

If the deviation is of moderate amount, not exceeding 20° on my point, it is expressed with sufficient exactness, for practical exposes, by the approximate formula.

 $\delta = A + B \sin \beta + C \cos \beta + D \sin 2 \beta + E \cos 2 \beta$ .

In this expression  $\delta$  is the deviation, reckoned + when and of the needle is drawn to the east, - when drawn to the is the compass course or the azimuth of the ship's head a direction of the disturbed needle, reckoned + to the east to the westward.  $\zeta + \delta$  is therefore the magnetic course azimuth of the ship's head from the direction of the magnet or of the undisturbed needle, reckoned + to the eastward, westward.

In this expression-

A is the constant deviation,

B sin f + C cos f form the semicorcular deviation;

D sin 2 t + E cos 2 t' give the quadrantal deviation,

When the compass is on the middle fore and aft line of .he coefficients A and E are generally so small that they may be not the expressions for the deviation then becomes—

δ = B sin s' + C cos s' + D sin 25'

In this case, therefore, there is no constant deviation semicircular deviation is B sin \$\(\zeta + C\) cos \$\(\zeta\); the quadrantal cos \$\(\zeta\).

Again. B is approximately the deviation at east; and changed sign, at west. C is approximately the deviation at and, with changed sign, at south. D is the mean of the deat N E, and S.W.; and, with changed sign, at S E and N.W.

The coefficients A, R, C, D, E, are best determined observations of deviation made with the ship's head on a number of equi distant points. When we can observe only on number of points equally distributed round the horizon it is not use in every case the following exact expression for the deviation.

2 Exact formula, to be used when the deviation, on any course,

Sin  $\delta = \mathbf{A}$  cos  $\delta + \mathbf{G}$  sin  $\zeta + \mathbf{G}$  cos  $\zeta + \mathbf{D}$  sin  $(2 \zeta' + \delta) + \mathbf{G}$  cos  $(2 \zeta' + \delta)$  where the coefficients,  $\mathbf{A}$ ,  $\mathbf{G}$ ,  $\mathbf{G}$ ,  $\mathbf{G}$  are nearly, but not exactly, the natural sines of the coefficients  $\mathbf{A}$ ,  $\mathbf{B}$ ,  $\mathbf{C}$ ,  $\mathbf{D}$ ,  $\mathbf{E}$ .

3 Ship not on an even keel. When the ship heels over i' (+i' respecting a heel to starboard, -i' a heel to port) the approximate respon-

$$\delta = B \sin \beta' + C \cos \beta' + D \sin 2 \beta'$$

comes, very nearly,

- B sin  $f' = \left\{ C - (\frac{\pi}{2}) + \frac{\mu}{\lambda} - 1 \right\} \tan \theta i'' \left\{ \cos \frac{\pi}{2} + D \sin 2 \frac{\pi}{2} \right\}$ 

In this expression:  $\theta$  is the dip;

λ = Mean directive force of needle on board:

Directive force on shore.

Mean value of vertical force on board

Vertical force on shore.

The effect of the heeling is therefore to add to the deviation the term— $\{\mathfrak{F}+\frac{\mu}{\lambda}-1\}$  tan  $\theta$  is coa f=J is cos f, which is the heeling error, and J is called the heeling co-efficient.

When I'-90° or 270°, that is, when the ship's head is E or W. by compass, the heeling error 0; when I' 0° or 180°, that is, when the ship's head is N. or S. by compass, the heeling error—maximum. In

the northern beausphere, tan 8 being + and 150 + 1 - 1) being gen-

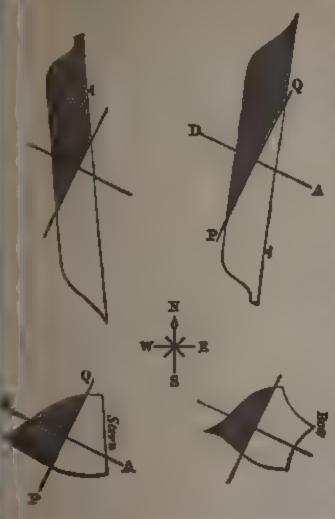

erally +, the heeling error will generally have the opposite sign to i\*, that is, will cause a deviation of the north point of the needle to windward.

Compass Deviation in Wood-built Ships. -The quantity of iron in these ships is comparatively small, it is in most cases equally distributed in both sides of the ship, and it is not exposed to mechanical violence after being fixed in its position on Hence, the disturbance it produces is small, the magnetism of one mass of iron counteracting, in a great measure, that of another, and the slight permanent magnetism of the ship has no general character. As a general rule, the deviation is at its maximum when the ship's head is near east and west by compass. The machinery of a steamer and the armament of a ship of-war introduce some modifications. The chief disturbing action of the iron in a woodbuilt ship arises from the magnetism which is transiently induced by the earth's magnetism giving rise to a semicircular deviation. Captain Flinders, at the commencement of this century, detected this: and, referring the changes in the errors of his compass on different sides of the magnetic equator to the induced magnetism in the vertical from stanchious ahead of the compass, suggested that this might be counteracted by a vertical from har introduced astern of the compass. This is the earliest recognition of the modern principle of compass compensation

## Compass Deviation in Iron-built Ships.

(1.) Disturbing Firees acting upon the Compass.

The influences causing deviations in the compass of an iron built whip are of two distinct characters. (1.) The ship itself is a tree

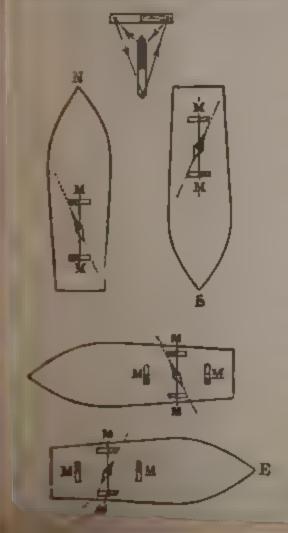

magnet, possessing sub-permanent magnetism, the position of its poles depending upon the direction of the ship while building. The annexed figures exhibit the magnetic condition of ships built the extreme positions, head north south, east and west. Red magnetism is shaded here with transverse QP as the lmes. equatorial plane, and AD the axis of terrestrial force or direction of dip. There are therefore three true magnets

considered: (a) The earth, the magnetism of which varies in and direction in different parts of its surface (b) the ship, is a constant magnet passing over this surface, quite adent of it, and turning its poles in all directions; and (c) the company needle suspended on board the ship, which thus with the needle's obedience to the terrestrial influence.

- (2.) Portions of the ship, such as vertical iron rods, which are often nearly in the direction of the earth's total force become transient induced magnets. Unlike the sub-permanent magnetism of the ship, this is dependent for the time being upon the terrestrial magnetism, and will vary with it in different parts of the world. In addition, then, to the three magnets, referred to above, we have (b) Portions of the ship which become transient magnets by induction of the earth. In the accompanying figures (p. 136) this induced magnetism is represented by the marked end being shaded longitudinally. N. and S. mean magnetic north and south.
- (II.) Resolution of Total Disturbing Forces into Horizontal and Vertical.—Just as the terrestrial magnetic force is resolved horizontally and vertically, the disturbing forces are resolved into corresponding components. These disturbing forces may be considered as equivalent to a permanent and induced magnet, and each is separately resolved into a horizontal and vertical component, the former being again resolved into two sub-components. The horizontal forces affect the direction of the compass needle directly, the vertical forces affect it indirectly, and the former are considered first. We have, therefore, the four component forces in order:
  - i 1, Horizontal Sub-permanent,
  - ii. 1. Horizontal Induced
  - i. 2. Vertical Sub-permanent.
  - ii. 2. Vertical Induced
- (III.) Principle of Compensating the Disturbing Forces.—The late Astronomer Royal Sir George Airy gives this in a few words:—"The only way of destroying the effect of one magnetic disturbing force is to introduce another disturbing agent, whose force follows the same laws and has the same magnitude, but always acts in the opposite

direction." Sub-permanent magnetism is corrected by the agency of a counteracting permanent magnet; and transient magnetism by counteracting masses of soft iron, which become similarly affected by induction, being converted into transient magnets. The horizontal components are corrected by magnets or masses of iron placed in horizontal positions; the vertical by magnets or masses of iron placed in vertical positions. These magnets and masses of iron are so introduced that their influence may neutralize the disturbing forces.

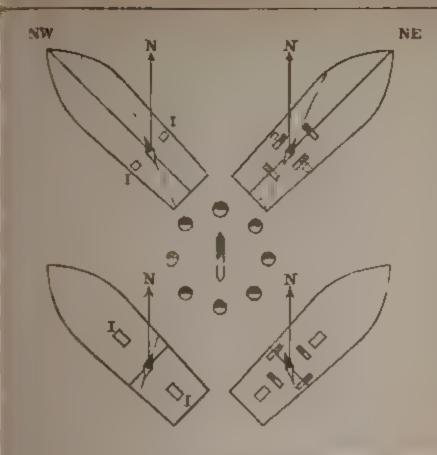

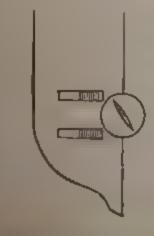

This is the general principle; the following are the different steps of the process.

(IV.) Method of Compensating the Component Disturbing Forces. -(i. 1 ) Harizontal Sub-permanent Magnetism. - This disturbance appears as a semicircular deviation, and the correction is made for direction of ship's head N. (which corrects it for S. also), and for direction of ship's head E. (which corrects it for W. also). For each of these two directions the compensation is effected by a magnet, or pair of magnets, which are always, when placed, transverse to the magnetic meridian. The process is represented in the annexed figures, where the dotted lunes. indicate the direction of the

affected by the semicircular deviation; the continuous lines the direction after the correcting magnets have been introduced. First placing the ship N. and S., we introduce the peedle magnets MM, causing them to approach gradually till the dotted line is made to coincide with the continuous one, or till the oscillations of the needle are equal on each side of it Next the ship is turned E. and W., and the deviation which then appears is corrected by a second magnet,, or pair of magnets (MM), placed as before, athwart the meridian. The first pair of magnets (MM) have no effect in this position, the action of the two sets being independent. The figure at the top of the diagram depicts the action of a compensating magnet

(ii. 1.) Herizontal Induced Magnetism.—This is the next component that should be corrected. It appears in the form of quadrantal upon the needle. deviation. When the ship is N and S, the induced magnetism of the iron on board produces no disturbance, and similarly when the ship is E. and W. The greatest effect is produced when the ship lies N.E. and S.W. or N W and S E, and therefore we must apply the compensation for these positions. If the correction be rightly effected on one quadrantal point it should be right for all. The effect of the horizontal component of the induced magnetism is, in the majority of cases, to draw the needle in the direction of the ship's length, but sometimes the needle is deflected towards a line drawn in the direction of the beam of the ship. In the figures we have shown both eases. The compensation is effected by the application of a mass or pair c masses of soft iron placed transversely to the direction of the limit towards which the needle is deflected, whether this be fore-andor athwart-ship. The figure in the centre of the diagram depicts the action of a mass of iron under horizontal industion in differ positions round the needle.

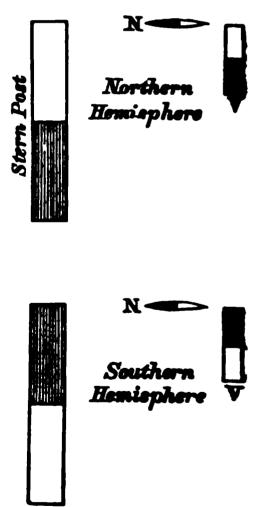

(i. 2.) Vertical Sub-permanent Magnetism.—This has no disturbing influence on the horizontal deflection of the compass needle so long as the ship is on an even keel, but, when she heels, a levial in results from it of sometimes I for every I of heel. The reason of this is evident, for what was obtacly a vertical force is now an oblique one

a portion of which is resolved in the horizontal plane, and this secondary horizontal component of what was originally the vertical component has an effect on the direction of the compass needle. A portion of the original horizontal force becomes at the same time vertical; so that it is strictly the effect of the difference that has to be corrected. This correction is effected by fixing a magnet or pair of magnets vertically below the needle, when the ship is on an even keel. Which end should be upward may be determined by considering the extreme case when the ship is on her beam ends, and when therefore the correcting magnet will be in the same horizontal plane with the compass needle; it can only be practically ascertained by the aid of a special instrument. The case shown in the figure requires the red end to be upwards.

- (ii. 2.) Vertical Induced Magnetism .-This is counteracted by introducing soft vertical rods which are affected by the same induction, but placed in positions where the influence on the compass acts in the opposite direction. The stern-post is one of the most powerful disturbing induced magnets on board a ship, its red end being downwards in northern magnetic latitude and upwards in southern The correction for magnetic latitude. this is made by placing a vertical rod of soft iron, V, ahead of the needle.
- (V.) Alternatives in Place of Compensating.—In the case of sub-permanent magnetism (i. 1. and i. 2.), the amount of the deviation depends upon the ratio of

the disturbing force to the terrestrial magnetism; and this ratio varies not only with the direction of the ship's head, but with her geographical position. The necessary corrections may be recorded in Tables, and applied to the indications of the compass; these tables being revised in different parts of the world.

In the case of induced magnetism (ii. 1.), the ratio which the disturbing force bears to the terrestrial magnetism (which induces it) is always the same, and therefore the amount of the deviation is the mme (for the same direction of the ship's head) in whatever part of the world the ship may be. The use of a Modified Compass Card obviates the necessity of either compensation or a table of corrections, for this part of the deviation. A practical objection to compensation by masses of soft iron, in some cases, arises from the large amount that would be required, and the close proximity of its position to the compass. The fact of the coefficient I) being found in all ordinary cases to be positive, led Staff-Captain F. J. Evans to propose the use of two Admiralty compasses of precisely equal strength, placed in starboard and port binnacles, regulated at a proper distance. The needles of these compasses will produce on each other a negative quadrantal deviation which will correct the positive quadrantal deviation arising from the ship. This mutual action of two proximate compasses was investigated in 1820, by Peter Lecount, Mid., R.N.

(VI) Practice in the Royal Navy.—A place for the standard compass, where it is least affected by the disturbing forces, is carefully selected on board. A magnet is generally introduced for the purpose of equalizing the directive force on different azimuths, and at the same time diminishing the semicircular deviation. The quadrantal deviation is corrected by means of soft iron spheres. The

heeling deviation is always ascertained, and is sometimes corrected mechanically.

Compass Deviations; Graphic Methods of Treating.
—See Napier's Diagrams and Curve; Dygogram.

Compass Bearing.—The bearing of an object as taken by the compass. It is distinguished from the true bearing, which may be deduced from it by applying the corrections for variation and deviation.

—See Bearing.

Compass Course.—The angle which the ship's track makes with the direction of the magnetic needle of the compass. It is distinguished from the true course, which may be deduced from it by applying the corrections for variation and deviation. The correction for treating is also necessary to deduce the course made good from the course steered.—See Course

Compass Error.—When the compass error is spoken of it is understood to mean the total amount of divergence of the compass needle from the geographical meridian, that is, the algebraical sum of the variation and deviation

Complement (L. complere, to "complete," "fill up."—The complement of a quantity is what must be added to it to make up a sum equal to some fixed quantity. The following are the special uses of the term.—

1. In Arathmetic.—The number 10, with its powers, is regarded as a standard of completeness, and the "arithmetical complement" of a number is the number which most be added to it to make it up to that power of 10 next higher; e.g. the ar co of 756 is 1000 - 756 = 244. This is used chiefly in problems worked by logarithms, the

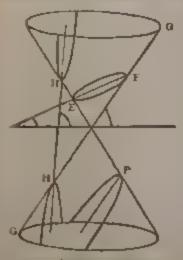

arithmetical complement of a logarithm being the difference between the logarithm and 10; e.g. the ar. co. of 3:460898 is 6:539102, the ar. co. of 2:636488 is 11:363512.

- 2. In Triyonometry.—A quadrant, right angle, or angle of 90°, is regarded as the standard of completeness; the complement of an arc or angle being the quantity which what must be added to it to make up the quadrant; e.g. the complement of 35° is 55°. Thus, the polar distance is the complement of the declination, or, as it is written, the co-declination; the zenith distance is the complement of the situade, or the co-altitude; and we also have the co-intitude. Again, the co-sinc is the sine of the complement, the co-tangent the tangent of the complement, the co-secant the secant of the complement.
- 3 In Geometry.—The complements of the parallelograms about the diagonal of a given parallelogram are those spaces which together with those parallelograms, "complete" the containing parallelogram.

Composite Sailing. A combination of preat-circle and parallel-sailing. A navigator, wishing to take the shortest route between two places, finds sometimes that in the particular case before him the great circle track reaches too high a latitude, where the ice renders it dangerous or impossible for the ship to penetrate. He therefore fixes upon some one parallel of latitude as the maximum; and the shortest route, under these conditions, will consist of a portion of that parallel, and of the portions of two great circles which are tangents to it, and which pass one through the ship, the other through the intended port. On the central or gnomome chart, the track will consist of the two straight lines drawn from the two places so as to touch the circle of highest latitude, and the part of this circle between the points of contact.

Con-, Co-, Com-, Col- (L. con, a prefix signifying "with." In the use of of this prefix before a vowel or h the n is dropped; and before l and m it is changed into these letters respectively). —An adjective with this prefix indicates that the things qualified possess the feature named in common: thus, concentric, having a common centre: co-axial, having a common axis; and similarly in co-extensive, co-incident, co-terminal and commensurate. There are also certain substantives in general use with the same prefix: thus, co-ordinates are a set of lines or planes disposed in a predetermined order, which taken together define the position of a point; a line of collimation in a telescope is the line of sight which brings together in one the centre of the object glass and the mid point of the cross-wires placed in the focus. Co is also used as a prefix before certain trigonometrical ratios, and arcs of circles. It is here the abbreviation of complement of, e.g., co-tangent, co-latitude.

Conic Sections. The curves formed by the intersection of a cone by a plane. They are of three kinds - the Parabola (Gk.

respective equations-

παραβάλλειν, " to place side by side "), the Ellipse (Gk. ελλείπειν, " to full short of "), and the Hyperbola (Gk. ἐπερβάλλειν, " to exceed "); in the first (P) the cutting plansis "parellel" to the generating line of the cone (GG), in the second (E) its inclination to the base is "less" than in the parabola, and in the third (H) it is in excess, hence the names. To persons acquainted with analytical geometry, the distinctive properties of the three are exhibited by their

$$y^2 = px$$
,  $y^2 = px - \frac{b^2}{a^3}x^2$ ,  $y^2 = px + \frac{b^2}{a^2}x^2$ 

be clipse is the most important to the nautical student.

Conjunction (L. conjunctio, from con, "together; "jungëre," to m. ')—Heavenly bodies are said to be in conjunction when they are the same longitude, and are therefore seen in the same part of heavens. In contradistinction to this, when they have a difference longitude of 180°, and are therefore seen in diametrically opposite at of the heavens they are said to be in opposition. For example: moon is in conjunction with the sun at new moon, in opposition full moon. The inferior planets (Mercury and Venus), instead of wing with the sun points of conjunction and opposition, have their terror and superior conjunctions—the former when the planet passes ween the sun and the earth, the latter when behind the sun mbols: Conjunction, 6; opposition, 8.

"Connaissance des Temps."—The French work corresnding to our "Nautical Almanac."

Constéllation (L. con, "together;" stellatio, "a grouping of its." from stella, "a star").—A group of fixed stars to which a finite name has been given. These names have mostly the origin the mythology of the Greeks, derived and modified from the options and the East; and the stars forming each configuration ranged and named in order of brilliancy by letters of the Greek habet attached to them—e.g. we have a Ursa Majoria, \$1000, etc. The districts of the heavens thus mapped out and ignated are entirely arbitrary, and in general correspond to no hard sub-division or grouping of the stars; and, as Sir John F. W. mohel remarks, "the constellations seem to have been almost

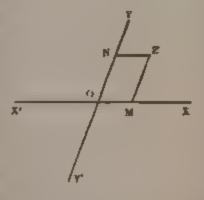

purposely named and delineated to cause as much confusion and inconvenience as possible. Innumerable snakes twine through long and contorted areas of the heavens where no memory can follow them; bears, hons, and fishes, large and small, northern and southern, confuse all nomenclature." This ancient system has, however, obtained a currency from which it would be difficult to dislodge it : and it serves the purpose of briefly naming remarkable stars-an important point for a navigator. These constellations are most conveniently studied under the three following groups :- (1) North Circumpolar Constellations, taking in 45° from the pole; (2) South Circumpolar Constellations, taking in 45° from the pole; (3) Equatorial Constellations, embracing a zone 45° north and 45° south One most conspicuous constellation above the of the equator. horizon in each of these will be sufficient to identify all the rest. In (1) we recommend Ursa Major; in (2) Cruz; and in (3) Orion and Lyra, these being in opposite parts of the heavens, and one of them. therefore, always above the horizon. These four constellations, taken as starting points, will enable a seaman easily to learn the position of any other group wanted

## Contraction of Moon's Semi-diameter. - See Moon.

Co-ordinates.—A set of lines, angles, or planes, or combination of these, which, taken together, define the position of the several points of a given surface, or points in space. The method was invented by Descartes, the French geometer, who first expressed algebraically theorems involving the position of lines. To represent the position of a curve on a plane, he chose a certain right line, to the different points of which he referred all the points of the given curve; then he chose a certain point in this line from which to

commence the reckoning ("ad ordiendam ab eo calculum"). Hence the series of lines by which the curve was referred to the chosen line were called ordinates (derived from a word of the same root, ordinare, "to range in order"), and the portions of the line "cut off" by this series from the chosen point were named abscises (L. abscindăre, "to cut off"). If, however, two lines are taken intersecting each other at a given angle in a fixed point, the several points of the curve in question may be referred to each of them in turn, and thus two sets of ordinates be contemplated, which, taken together, define every point of the curve; hence the term co-ordinates. 1. To explain linesty this system of rectilinear co-ordinates for a plane, XX', YY' are two fixed right lines given in position, intersecting each other in the point O. Let Z be any point in the plane. Through Z draw ZM

and ZN parallel to YY' and XX, then, if we know the position of the point Z, we shall have the lengths of ZM (y) and ZN (x); and vice versa, if we know the lengths of ZM and ZN we shall know the position of the point Z. In order to define in which of the four compartments about O the point Z is intusted, those distances which are measured from O to the right hand, and

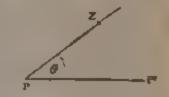

downwards, are regarded as positive, and those on the left hand, and downwards, negative. The parallels ZM and ZN are the co-ordinates, of the point Z; the fixed lines XX' and YY' are termed the axes of co-ordinates; and the point O the origin. A plane chart furnishes a good exemplification of the above. XX' and YY' intersecting at each angles will represent respectively the equator and first meridian,

and the co-ordinates of any place on the chart will be its longitude and latitude.

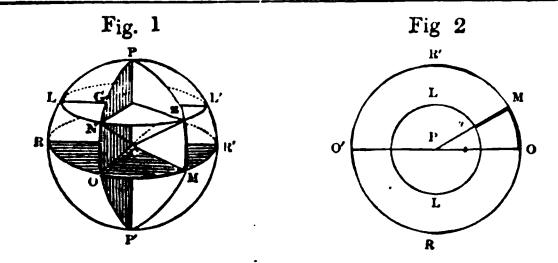

2. Polar system of co-ordinates .- P is a given fixed point called

the pole, and PP a fixed line through it. Then we shall know the position of any point Z if we know the length of PZ, and also the angle PPZ. This line PZ is called the radius vector  $(\rho)$ , and the angle PPZ the polar angle  $(\theta)$ .

The angle is reckoned positive when the radius vector revolves in the direction opposite to that in which the hands of a watch move, negative when it revolves the contrary way.

Co-ordinates for the Surface of a Sphere. - The great circle is to the surface of a sphere what the straight line is to the plane. Hence, by substituting "sphere" for "plane," and "great circle" for "right line," in the last article, we shall have no difficulty in understanding how the position of a point is defined by co-ordinates on this surface. 1. To follow Descartes' original words when describing rectilinear co-ordinates. Let a certain great circle RORO be chosen, to the different points of which any point of the sphere may be referred thy arcs of great circles perpendicular to it); then let a certain point (0) be chosen in this great circle from which to commence the reckoning. Thus, the position of the point Z is defined by the arcs of great circles OM and MZ. Here we have the conception (explained in the last article, fig. 1) of ordinate and abscissu, and hence the usual method of naming the great circles used to refer points to the fixed great circle. They are named after the ordinate which is measured on them. 2. But, as it is useful to regard the sphere as a surface generated by the revolution of a circle about one

of its diameters, the conception of polar co-ordinates is especially applicable and convenient. The angle through which the generating circle revolves is the polar angle, and an arc of this circle the radius vector. Thus—Let PP' be the diameter of the generating circle, one of the extremities of which (P) may be regarded as analogous to the fixed point P in the polar co-ordinates for a plane (fig. 2 of last article), the fixed great circle POP analogous to the fixed right line PP', and the great circle arc PZ analogous to the radius vector PZ. Thus the point Z is defined by the angle OPZ and the arc PZ. In this view, the circle passing through Z, being the generating circle in a particular position, would be naturally named after the angle swept out from its initial position.

The two conceptions may be advantageously combined. The ordinate circle of the first system is the same as the generating circle of the second system; the ordinate and radius vector coincide in direction and are complementary to each other, and are thus convertible, and the abscissa and polar angle measure each the other, and can hence be interchanged. The surface of a sphere is a limited one, analogous not to an indefinite plane, but to a circular direc-

And just as in such a circular disc we may reckon a distance on tae radius vector, either from the centre (the pole) or by its complement in the opposite direction from the circumference, so on the surface of a sphere we may recken the distance of a point on the generating circle either from the pole or from the pole's great circle. If we adopt the latter plan, we find we have substituted ordinate for polar distance. Again, on the surface of a sphere, the angle at any point and the corresponding are of the great circle of which this point is a pole may be used indiscriminately for each other; ie the polar angle and the are of the fixed great circle intercepted from the origin (the thecosar are virtually the same thing. The use of co-ordinates for the surface of a sphere may hence be comprehensively described as follows. A fixed great circle RORO' is chosen as the primitive, and another fixed great circle POPO at right angles to this represents the unitial position of the accordary. These two circles intersect in two fixed points O and O, which are called the points of origin accordary circle, or rather one-half of it, POP', is now conceived to revolve upon the axis PP from its initial position. In any given position PMP, it will mark out all points of a sphere which have the same polar angle OPM, or the same abscusa OM. Again, in thus revolving, any point in its arc will describe a small circle parallel to the primitive, which parallel will mark out all points of the sphere that have the same radius vector or polar distance PZ, or the same ordinate MZ. The intersection of the two, the secondary and the parallel, gives the point Z. It being known, therefore, whether only one (O) or both (O and O) of the points of origin are to be reckoned from, and in which direction the secondary is to revolve, and again, on which side of the primitive the parallel hea, the position of any point Z is completely defined by its co-ordinates, the polar angle OPM, or the abscissa, the arc OM (=angle at centre OCM), and the radius vector PZ, or the ordinate MZ (=angle at centre MCZ)

The two spherical surfaces with which the navigator is concerned are those of the terrestrial sphere and the celestial concave.

Co-ordinates for the Terrestrial Sphere. —Co ordinates, Longitude and Latitude. The primitive (ROR'O') is that great circle perpendicular to the axis of the earth's rotation-the Equator; the secondary semicircle (POP), in its different positions, generates the Meridians or Circles of Longitude, each of which (as PMP') marks all the places that have the same Longitude (as OM); the initial position of the secondary (called the First Meridian) is variously determined by different nations from the station of their principal observatory (G); and the secondary is commonly conceived to revolve westward and eastward through 180°; the parallels, called Parallels of Latitude (se LNL'), mark all the places that have the same Latitude north or south (as ON). Any place (as Z) is defined by the intersection of its circle of longitude (PMP) and its parallel of Littude (LNL'), and its position described by its two co-ordinates, longitude (east, O M) and latitude 'north MZ). When the spheroidal figure of the earth is taken into account, a new definition of latitude is necessary [Latitude of an Observer].

Note — Longitude is usually, as above noticed, reckened west and cost. High authorities, however, recommend that this mode of expression should be abandoned, and longitudes reckened invariably westward from their origin round the whole circle from 0 to 360°. This would add greatly to systematic regularity, and tend much to obviate confusion and ambiguity in computation. When the secondary is regarded as an ordinate rather than a polar circle, the mendians will be called Circles of Latitude.

Co-ordinates for the Celestial Sphere. In what follows, the system takes its title from the primitive, and the secondary is viewed as a generating circle:—

- 1. Ediptic System. Co ordinates to describe the points of the celestial concave relatively to each other, and with primary reference to the proper motions of the heavenly bodies—Longitude and Latitude. The primitive circle (RORO) is the apparent path of the sun in the heavens,—the Ediptic; the secondary semicircle (POP) in its different positions generates the Circles of Longitude, each of which (as PMP) marks all the points that have the same Longitude, (as OM); the initial position of the secondary is defined by the Vernal Equinoctial Point; and it revolves eastward through 360°; the parallels, called Parallels of Lotitude (as LNL), mark all the points that have the same Latitude north or south as ON). Any point (as Z) is defined by the intersection of its circle of longitude and its parallel of latitude, and its position is given by its two co-ordinates,—longitude (OM) and latitude (north, MZ).
- 2. Equinoctial Systems.—(a) Great-circle co-ordinates to describe the points of the celestial concave relatively to each other, and with primary reference to the apparent diurnal motion of the heavenly bodies,—Right Ascension and Declination. The primitive circle (RORO) is that great circle perpendicular to the rotation axis of the heavens,—the Equinoctial; the secondary semicircle (POP) in its different positions generates Circles of Right Ascension, each of which (as PMP) marks all the points that have the same Right Ascension (as OM); the initial position of the secondary (called the Equinoctial Column) is defined by the Vernal Equinoctial Point, and it revolves eastward through 24h or 360°; the parallels, called Parallels of

Declination (as LNL'), mark all the points that have the same Declination north or south (as ON). Any point (as Z) is defined by the intersection of its circle of right ascension (PMP') and its parallel of declination (LNL'), and its position is given by its two co-ordinates,—right ascension (OM) and declination (north, MZ).

- (b) Polar co-ordinates to describe the points of the celestial concave with reference to the diminal motion of the heavenly bodies and in connection with the position of an observer on the earth's surface,—
  Time or Hour Angle and Polar Distance. The initial line is the Noon Circle, or, as it is commonly called, the Celestial Meridian; the radius vector is the Time Circle, or, as it is commonly called, the Hour Circle, and the polar angle is the Time Angle, or, as it is commonly called, the Hour Angle. The noon circle, or celestial meridian is defined by the meridian of the place or the zenith of the observer; the time circle revolves from the initial position westward through 24b; on the time circle is measured the Polar Distance from the elevated pole through 180°.
- 3. Horizon System.—Co-ordinates to describe the points of the celestial concave with reference to the position of an observer on the earth's surface,—Azimuth and Altitude. The primitive circle (ROR'O') is that great circle in which a horizontal plane through the observer's eye meets the celestial concave, and which derives its same from its being the "boundary" of the visible and invisible hemispheres,—the Horizon; the secondary semicircle (POP'), in its different positions, generates the Circles of Azimuth, each of which (as PMP') marks all the points which have the same Azimuth (as OM); the initial positions of the secondary are defined by the North or South Point (that one which is most remote from the elevated pole); and it revolves eastward and westward from 0 to 180°; the parallels,

COR CAROLI.

Med Parallels of Altitude, (as LNL'), mark all points that have the ane Altitude, positive or negative (as ON) Any point (as Z) is defined by the intersection of its circle of azimuth and parallel of Stitude, and its position is described by its two co-ordinates-

When a body is in the horizon, its position is described by its azumuth (OM) and altitude (+MZ). distance north or south of the east or west point, which is called its

Note. - If, in the above, the secondary in its different positions were viewed as one of a series of ordinate circles (after the analogy of rectilinest co-ordinates), then these circles would be named after the ordinate Amplitude. which is measured on them We should thus have "circles of declination," "circles of latitude," "circles of altitude." But we have regarded the secondary as a generaling circle, and named it after the angle it aweeps out from its initial position, as in polar co-ordinates The advantage of this method is, that each of these oircles thus marks out all points which have the same right ascension, the same longitude, the same azumuth, as the case may be, just as in the series of small circles parallel to the primitive, each parallel marks out all points that have the same declination, the same latitude, the same ultitude, as the case may. Thus also is insured the meutice of both, instead of one only of the co-ordinates. For example : A point is defined by the intersection of its circle of right ascension and its parallel of declination, which is a more complete form expression than to say it is defined by the intersection of its circle declination and its parallel of declination

Cor Caroli (L. "Charles's Heart") -The name given by Hall to the star 12 Canum Venaticorum. - See Canes Venatici.

Corona Borealis (L. "The Northern Crown") —A constellation lying between a Lyrr and Arcturus. It consists of six or seven stars, forming a small semicircle—a Corona Borealis (called also Gemma), mag 24. N.A. 1896; R.A. 15h 30m. Dec. + 27° 4′

Corrected Establishment of the Port.—The interval between the time of the moon's transit and the time of the high water at the port corresponding to the day of syzygy. It is distinguished from the Vulgar Establishment of the Port, which is the interval between the time of the moon's transit and the time of high water on the day of syzygy.—See under Tide.

Corrections. - Corrections are quantities which have to be applied to observed elements before these can be made the subject of computation in the various problems of navigation. Thus in geonavigation, in a day's work, we want to find the total true course made good; for this computation we should have all the several true courses made good during the day; but those which we have noted were the compass courses steered. These compass courses steered must therefore be reduced to the corresponding true courses made good, and this is done by applying the "corrections" for variation, deviation and leeway So in the problems of celo-navigation, such elements as the altitudes and distances of heavenly bodies are used. But these are observed with an instrument which may have an index error; the observer is generally elevated above the earth's surface; and often one of the limbs, instead of the centre of the body, is observed. Such an observed element therefore requires the "corrections" for milex error, for dip, for semidiameter. But, further, the atmosphere variously affects such observed elements; and the different positions of observers on the earth's surface must be taken

observations must be transformed into what they would have been had the bodies been viewed through a uniform medium, and from one common centre—the centre of the earth; hence the additional corrections for refraction and parallax. It is, however, only a few elements that are the subject of direct observation on board slap; others, as the declination and right ascension, are found by consulting the Nantical Abnanac. They are there tabulated for certain Greenwich dates. But, before, we can use them in our calculations, they must be reduced to what they would be if observed from the ship's place at the instant under consideration. A simple proportion will generally enable us to do this; and the process is called "correcting" the declination, right ascension, etc.

Course.—The course is the direction in which a ship sails from one place to another, this direction being referred to the geographical meridian, which lies truly north and south, to the magnetic meridian of any place or to the position of the compass needle by which the ship is steered. The former is distinguished as the True Course, the second as the Correct Magnetic Course, and the last as the Compass Course. The course is reckoned from north towards east and west when the ship's head is 'ess than eight points from the north; and from south towards east and west when the ship's head is less than eight points from south

In rhumb sailing the course is constant, and is the common angle which the track makes with the meritians lying between the place left and the place sought. It is reckoned from the north point, towards the east and west, when the ship's head is less than eight points from the north; and similarly for the south point. In great-circle sailing, the course is being constantly changed.

Course and Distance.—Problem in geo-navigation. To the course and distance between two places of known latitude and longitude. Two general methods of solution.

1. By "meridional parts"; from the formulæ—

(a). Tan Course = 
$$\frac{\text{Diff. long.}}{\text{Mer. diff. lat.}}$$

- ∴ L tan course 10 = log diff. lat. log mer. diff. lat.
  - (b). Distance = True diff. lat.  $\times$  sec course.
  - ∴ log dist. = log true diff. lat. + L sec course 10
- 2. By "middle latitude"; from the formulæ-

(a). Tan Course = 
$$\frac{\text{Dep.}}{\text{True diff. lat.}}$$
  
=  $\frac{\text{Diff. long.} \times \cos \text{mid. lat.}}{\text{True diff. lat.}}$  (nearly)

- .. L tan course = log diff. long. + L cos mid. lat. log true diff. lat. (b). Distance = True diff. lat. × sec course.
  - $\therefore$  log dist. = log true diff. lat. + L sec course 10.

In the case of parallel sailing the course is due east and west; and the distance is found from the formulæ—

Distance = Diff. long.  $\times$  cos lat.

 $\therefore$  log dist. = log diff. long. + L cos lat. - 10.

The shortest distance, and the varying courses required for lowing this shortest track, may be found by the rules of greatle sailing.

Course and Distance, Current.—The course and distance the is equivalent to the effect of the drift and set of the current in haship is sailing.—See Current.

Instance, Departure,-The course and is supposed to have made from a landmark and latitude to the spot from which she actually L criptra, "doubtful"; har, "hight"). - A its plane parallel to that of the horizon, at about sun is between this parallel and the horizon during The hearings of two or more objects taken Place, and therefore intersecting or "crossing" each taff -An ancient metrument for taking altitudes and sea. It consisted of a straight square graduated staff tasoms leach with square socket) sliding on it. The arms pieces or vanes were of different lengths. the ten-cross aged to the side of the staff which was graduated towards and up to 10°; the thirty cross vane belonged to the side as graduations were from 10° to 30°; the sixty-cross vane to here they were from 30° to 60°; the ninety cross vane where the front 60° to 90°. The graduations were "the natural the half cross being radius." This ment was also called the Fore Staff and Jacob's Stoff TOBB-Wires .- Spider wires placed in the focus of the object of an astronomical telescope. In this position they become fole by stopping pencils of rays, which there converge to points. this focus, also, the image of a heavenly body as it passes over the of view is seen, and its place is noted by referring it to the crow Orossed Observations.—("Observations croiseés,"Borda).—
using Borda's repeating reflecting circle a series of pairs of
mervations is taken—the first of each pair with the instrument
and in the direct position, the second with it reversed. The
oving vernier thus passes over double the angle to be measured,
dex error being eliminated. The directions of the moving reflector
the two observations cross each other, passing between them
brough the position of parallelism with the fixed reflector.—See

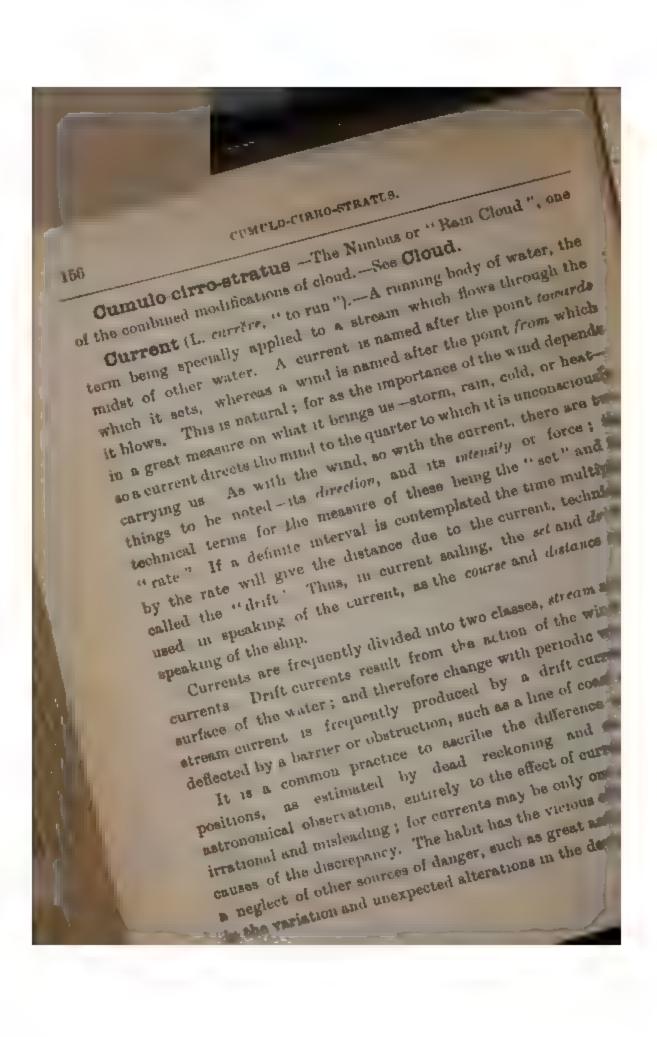

orcle, Borda's.

Crux (L. "The Cross").—A constellation which, together with ataurus, constitutes a bright group in the southern hemisphere, inted to by the fine joining Arcturus and Spica. a Crucis mag. 1.3, A. 1896; R.A. 126 21m, Dec. - 62° 31'.

Culminations (L. culmen, "the top," "ridge").—The heavenly dies in their diurnal revolution, when they attain their greatest their least altitude above the horizon, are said to culminate; happens when they cross the merchan. All those bodies which within the circle of perpetual apparition visibly come to the ridian twice in every diurnal revolution, once above and once the elevated pole. These are respectively called their Cipper Lower Culminations. Such bodies have a Polar distance less the latitude of the place. Bodies whose Polar distance is ster than the latitude of the place, but not so great as to prevent it rising at all, culminate only once.

Cumulus (L. "a heap"). -The "Heap-Cloud", one of the mary mochfications of cloud. -See Cloud.

Cumulo-stratus. —One of the combined modifications of cloud.

Current Charts.—A Mercator's chart with the currents marked upon it will afford the navigator much assistance in making passages. An admirable one is contained in "Wind and Current Charts for Pacific, Atlantic, and Indian Oceans", published by the Hydrographic Office in 1872. Wavy lines and arrows are used to indicate the general direction of the current, and its minimum and maximum rates are attached in figures. A supplementary chart is given for that part of the Indian and China seas where a change in the Mousoon brings about a corresponding change in the set and drift.

Current Course and Distance.—The set and drift of a current treated as a course and distance in the day work. The current is known beforehand from charts and sailing directions. It must be carefully noted whether the true or magnetic set is thus given, in order that the current course may be corrected if necessary.

Current Sailing.—When a ship is sailing through a sea in which there is a current, the effect of this current will be to set her in a certain direction and drift her at a certain rate. The consequent change in her position may be found by considering the set and drift as a course and distance, which are called the current course and distance. The motion due to the action of the current goes on simultaneously with the sailing of the ship over a given distance on her prescribed course; but the two may be treated separately, and a traverse worked to obtain the combined result. Current sailing is thus reduced to a case of traverse sailing.—See Sailings.

Curvature (L. curvatura, "a bending").—The amount of bending of a curve from its tangent at any point. As the curvature

the circle is uniform, it is used as the measure of the curvature of The osculating (i.e. "kissing") circle to a curve at ven point is called the circle of curvature. Again in the circle, the effection from the tangent corresponding to a unit arc is inversely proportional to the radius; hence the reciprocal of the radius of circle is the measure of its curvature, and the radius of the circle of curvature (radius of curvature) consequently defines the curvature of The curvature of a surface at any point is determined by that of the plane sections through the Point. The above consideration is important in connection with the figure of the earth.

Oyclones (Gk. Kûklos, "a circle").—Rotatory storms ( Geographical.

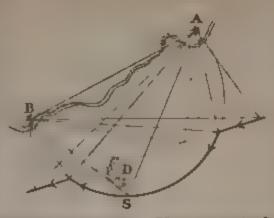

circular motion, is used specially for those of the Indian Ocean whirlwinds.

Oygnus (L. "The Swan").—A constellation between Lyr Pegasus. The principal star, a Cyyni (called also Deneb), m See Storms, Law of. found also by joining γ and β Peyasi and producing it to about its length. Mag. 1.5, N.A. 1896; R.A. 20h 38m, Dec. + 44° F

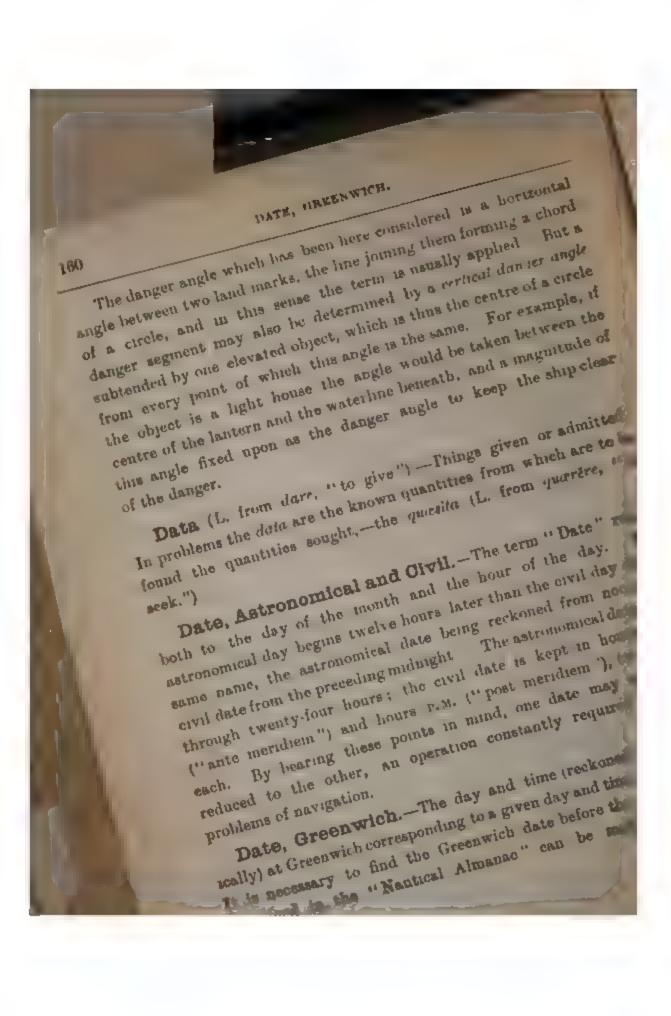

d.—Among the letters used to register the state of th

in the log-book, d denotes "Drizzling Rain." Danger Angle.—The angle subtended by

point S is fixed upon to seaward giving the nearest safe distance a ship can approach the danger D, then the angle subtended at this spot by the two objects A und B is called "the danger angle." Having marked the point S on the chart and joined SA, SB, the angle ASB may be

measured by a protractor and set upon the sextant. If a segment of a circle be described on AB passing through S, then at every point on this are ASB the angle subtended by A and B will be the same, (Euc III 21). Therefore, as long as the angle at the ship subtended by A and B remains constant she is on this are and in safety: if the angle diminishes, the ship is outside "the danger segment" and is sailing well clear of the danger : but if the angle increases it indicates that she is within the danger segment and will probably be stranded if in the vicnimity of D. The angle ASB is really the "safety angle," but it is usual to call it "the danger angle," its magnitude having been chosen to protect the ship from running into danger. It is descrable to fix upon convenient land-marks beforehand for the dangers lying near the ship's course on a voyage, and have the danger angles tabulated for use when required. In doubling a promontery with outlying reefs, this danger angle will enable the navigator to double it with the greatest advantage, passing at the shortest distance consistent with safety. In running along a coast which is washed by shallow water for a considerable distance, a series of land-marks should be chosen, each successive pair giving a new danger angle which can be put on the sextant in turn as a mark passes astern,

because all the elements there tabulated are given for time at the meridian of Greenwich. It is deduced from the ship date by applying the longitude in time

Day .- tenerally, the time occupied by a rotation of the earth on her axis, as indicated to a spectator on the earth itself by the corresponding apparent revolution of the celestial concave, more particularly, some point (which may either be fixed, or have a proper motion of its own) must be taken to mark its commencement and period, which we call the "point of definition," and the choice gives rise to a distinction of several kinds of days, which differ from each other slightly in length. (1) If the first point of Aries (to which the positions of all the stars are referred) be taken as the point of definition, we have what is called a Siderral Day , (2) If the actual sun's centre be taken as the point of definition, we have the Apparent "clor Day, (3) If the centre of the fictitious mean mun be taken as the point of definition, we have the Mean Solar Day; (4) If the moon's centre be taken as the point of definition, we have a Lunar Day These are all included under the term Astronomical Day, as distinguished from the Civil Day and the Nautical Day, The scientific term "Day" is never used in the sense of day as opposed to might.

Day, Astronomical.—The day used by astronomers to which to refer their observations, being distinguished from the Civil day which regulates the ordinary business of life. The astronomical day begins at noon, and ends at noon, its hours being reckoned from 0h to 24h; the civil day begins at midnight and ends at midnight, its hours being reckoned through twice twelve. The astronomical is later than the civil day by twelve hours. The cause of this

inconvenient difference in the modes of reckoning is, that astronomers carry on their observations chiefly at night, and if they, therefore, adopted the civil method of reckoning, they would have to change the date at midnight, the former and latter portions of every night's observations belonging to two differently numbered civil days of the month. It has, however, been questioned whether this inconvenience would be as great as that resulting from the present neglect of uniformity in reckoning time. According to the point of definition chosen [Day], the Astronomical Day is either a Sidereal Day, an Apparent Solar Day, a Mean Solar Day or a Lunar Day; the term, when used alone, is usually understoood to refer to the "Mean Solar Day." Reckoning in mean solar time, which is the same as civil time, a mean solar day is 24h, a sidereal day 23h 56m 4 09s, and an average lunar day 24h 54m.

Day, Sidereal. The interval between two successive transits of the first point of Aries over the same meridian, the first point of Aries being the origin to which the positions of all stars are referred. This is called a subcreat day, although not strictly determined by the stars; but the very slow motion of the first point of Aries, relatively to the stars, makes this day practically the same as if a fixed star had been taken, for if two clocks be set, the one on the first point of Aries, the other on the fixed star, so as always to mark 0h 0m 0s when the point or the star respectively comes to the meridian, the difference of the two clocks would only be about 3s in the whole year. The length of the sidereal day in mean solar time (which is the same as civil time) is 23h 56m 4 09s, the ratio between it and the mean solar day being as 1 to 1 00273791. The sidereal day is divided into twenty-four sudereal hours, and these are again subdivided into manutes and seconds.

Day, Solar.—The interval between two successive transits of the sun's centre over the same meridian. The Apparent Solar Day varies in length in consequence of the variable motion of the sun in the ecliptic, and of the inclination of the ecliptic to the equator; hence the necessity of inventing a uniform measure of time—the Mean Solar Day.

Day, Apparent Solar.—The interval between two successive transits of the actual sun's centre over the same meridian; it begins when that point is on the meridian. The apparent solar day is variable in length from two causes: first, the sun does not move uniformly in the ecliptic its apparent path sometimes describing an arc of 57, and at other times an arc of 61 in a day; secondly, the ecliptic twice crosses the equinoctial—the great circle whose plane is perpendicular to the axis of rotation—and hence is inclined differently to it in its different parts; at the points of intersection the inclination is about 23° 27°, at two other limiting points they are parallel. A uniform measure of time is obtained by the invention of the Mean Solar Day.

Day, Mean Solar.—The interval between two successive transits of the mean sun over the same meridian; it begins when the mean sun is on the meridian. This fictitious body is conceived to move in the equinoctial with the mean inction of the actual sun in the coliptic. The length of the mean solar day is the average length of the apparent solar days for the space of a solar year

Day, Civil.—The day used for the ordinary purposes of life. The motion of the sun in the heavens, bringing the alterations of light and darkness, determines generally our social arrangements, and time being kept by mechanism, the day must be of invariable

## DAY, CIRCUMNAVIGATOR'S.

Hence the civil is of the same length as the mean sclar day It differs, however, from the astronomical mean solar day in the following points. The astronomical day begins at noon and ends at Doon, its hours being reckoned from 0h to 24h; the civil day begins at undnight, and its hours are reckoned through twice twelve, from inidught to noon (ante meridiem, A.M.), and then from noon to The commencement of the astronomical day is placed twelve hours later than that of the civil midnight (post meridiem, PM,).

Day, Nautical -In the Royal Navy the Nautical Day to the some in every respect, and divided in the same manner, as the Civil Day on shore Thus a page of the log book is ruled so as to day commence and end with midnight, and is divided into two parts by noon As the reckening, however, is made up to noon each day, for convenience the log board, or page of the rough deck log, was sometimes arranged so as to begin and end with noon. This is still the custom in the Merchant Service, even in the permanent log book; the nautical day is (like the astronomical) made to begin at noon, and the hours are carried on to twelve at midnight, and thence, commencing afresh, to twelve the next noon. Hence the remark which is usually found in the last page of the harbour log - "This day contains twelve hours to commence the sea log." It would be well if the Merchaut Service would uniformly follow the example of the Royal Navy, and adopt civil time for civil purposes, at ies an

Day. Circumnavigator's.-A ship sailing westward run away from the san in his diurnal course, and, when she has circum well as in harbour navigated the globe, the sun will evidently have crossed her meridies cace less frequently than if she had remained stationary.

contrary, a ship sailing eastward meets the sun in his diurnal course, and, when she has circumnavigated the globe, the sun will evidently have crossed her meridian once more than if she had remained stationary. Hence a westwardly circumnavigator loses a day in his reckoning, an eastwardly circumnavigator gains a day. The alteration of the date, by inserting a day or leaving out one in the ship's log book, should be made on crossing the meridian of 180°

Day, Intercalary. The day that is intercalated or inserted in the calendar in leap year to make up for the odd hours, minutes, and seconds of the tropical year which have been left out in making the civil year to consist of 365 integer days.—See Calendar.

Day's Work.—The work of computation required in navigating a ship for every twenty-four hours. The term is generally restricted to the dead reckoning. At each noon the true course and distance made good, the latitude and langitude, and the compass betting and distance of the point which is to regulate the ship's course during the next twenty-four hours, are wanted. The data for this work are the latitude and longitude at the preceding moon, the compass courses and distances run on each course during the last twenty-four hours, the variation of the compass, the deviation of the compass for the various directions of the ship's head, particulars of the direction and force of the wind with the consequent leeway, and the set and drift of the current if any. The term "Day's Work" may, however, be understood to comprise all the computation which the navigator regularly makes every day, and the results of which he inserts in the log book.

Dead Reckoning.—Referred to by the initials D. R. The account kept of the ship's place from results obtained by the methods of geo-navigation only, as distinguished from the account deduced

from astronomical observation. Dead reckoning thus takes cognisance of Hearings, Soundings, and Loggings. In practice the methods of geo navigation and celo navigation are combined; and in working the dead reckoning it is usual to find the latitude at noon on any day, by applying the difference of latitude made good by the ship in the preceding twenty four hours, to the latitude by observation (when an observation has been obtained) of the preceding noon.

Decamètre (Gk. 8éxa, "ten"; Fr. mètre).—A French measure of length, consisting of ten mètres, and equal to 393.71 English inches.

Decimètre (L. decima, a "tenth". Fr. mêtre).—A French measure of length; a tenth part of the mètre, and equal to 3 937 English nuches.

Declination of a Heavenly Body (L. declinatio, ". learning, ' a deviation in a lateral direction) - The angular distance of the body from the equinoctial. It is measured by the arc of an ordinate circle secondary to the equinoctial, which is intercepted between the equinoctial and the place of the body, or by the corresponding angle at the centre of the sphere. Declinations are rackoned from 0 to 90" North (N.) and South (S.) to the poles. often convenient to regard them as positive (+) or negative (-), according as they and the elevated pole are of the same or different In the List of Fixed Stars in the "Nautical Almanac," North declinations are designated positive (+) and South declinations The complement of the declination is the polar Right ascension and declination are the equinoctial coordinates for defining the positions of points on the celestial concave and indicating their positions relatively to each other. - See Co-ordinates for the Celestial Sphere.

Declination, Circles of.—Great circles of the celestial concave perpendicular to the equinoctial; and so called because the ordinate "declination" is measured upon them. When polar co-ordinates are contemplated, this system of circles is called "Hour Circles" and "Circles of Right Ascension," as marking out all points that have the same hour angle and the same right ascension.

Declination, Parallels of.—Lesser circles of the celestial concave parallel to the equinoctial. They mark all the points of the beavens which have the same declination. Compare "Parallels of Latitude," "Parallels of Altitude."

Declination of the Compass Needle.—A term sometimes used by scientific men for the "Magnetic Variation" of the needle, and found in that sense in the instructions given by the Council of the Royal Society to Captain Sir J. C. Ross, on his expedition to the antarctic regions. Raper strongly protests against the term as introducing confusion into the vocabulary of practical seamen.—See Magnetic Needle.

Deep Sea Lead.—The instrument used for sounding in deep water.—See Sounding

Definitions.—A definition is a description in which two points must be attended to: First, it must exclude everything but what is under consideration; and Secondly, one essential property only must be mentioned—others which can be deduced from this are superfluous. Thus we want a definition of the Celestial Mendian, If we say, "The Celestial Meridian is a great circle of the celestial concave which passes through the zenith"; this is true, but it includes every other vertical circle, and therefore is not a definition

of the meridian. Again, if we say, "The Celestial Meridian is a vertical circle passing through the poles and the north and south points"; the whole of this is true, but the mention of all these properties is superfluous, and therefore to be avoided. Any of the following descriptions, however, is a correct definition, and one is to be preferred to the others only on account of its relation to, and uniformity with, the other debattions in the system we adopt : "The great circle of the celestral concave passing through the elevated pole and the zenith"; "The hour-circle passing through the zenith"; "The vertical circle passing through the elevated poles"; " the circle of azimuth passing through the north or south point "

Degree (L. gradus, "a step"; Fr. degre) - The angle subtended at the centre of a circle by an arc equal to the 360th part of the circumference. Each degree is subdivided into 60 minutes, and each minute into 60 seconds. As these are also the subdivision of periods of time-the hour and the minute -it seems probable that the division of the circle into the number 360 had reference to the space described by the sun in one day, in performing his aunual revolution. The round number 360 was doubtless adopted for convenience as containing a greater number of divisors; but the origin of the arrangement is perpetuated in the Chinese system where the circle continues to be divided into 3651 degrees, one such space being described by the sun daily.

Degree of Latitude. - A degree of Latitude on the earth's surface has been defined to be the distance an observer must advance along the meridian, in order to experience a change of one degree the elevation of the pole. A comparison of measured lengths of the degrees of the meridian, at different latitudes, furnishes the mean deducing the true figure of the earth.

Degrees of Longitude.—A caution is necessary against calling the minute of a degree of longitude a mile. The length of a minute of a degree of longitude varies in different latitudes, whereas a mile is a measure of invariable length.

Degree of Dependence.—The practical aspect of the limit of probable error in the computations of the navigator. All the elements which form the data of his problems are more or less uncertain; some of them have to be ascertained more accurately than others, and, under certain circumstances, a slight error in an observed element produces a much greater effect in the heal computed result, than under other circumstances. The knowledge of the degree of dependence in each case is indispensable in forming a right judgment of the area within which we are sure the true place of the ship lies; the principle should always regulate the amount of labour to be bestowed on the work of different parts of the computation.

Denob.—An Arabic word signifying the tail. It is used to designate a bright star in the tail of some of the constellations. Thus a Cygni is called Deneb; β Leonis is called also Denebolo, or sometimes simply Deneb, there is also Deneb Aligedi in Capricornus. It were well if the word fell into disuse.

Departure.—If the rhumb-line be drawn between two places on the earth's surface, and points be taken on it indefinitely near to each other, the departure is the sum of the in lefinitely small arcs of the parallels of latitude drawn through them intercepted between each of the points and the meridian passing through the adjacent one. It may be regarded as the distance in nautical nules made good due east or due west by a ship following a constant course, and is marked east (E.) or west (W.) according as it is made good towards the east

DEPARTURE.

In the former case it is also called " Easting," to the latter " Westing." When the two places are on the same parallel, the departure is identical with the distance. When the places do not differ much in latitude, and are on the same side of the equator, an approximation to the departure is found in the arc of the Parallel of middle latitude included between the meridians of the two places. It must be borne in mind that the departure is expressed in miles, and not, like the longitude, in arc. The departure is connected with the distance and course by the relation. - Departure = Distance x Sin Course. - See Rhumb Sailing, Fundamental

Definitions, and Fundamental Propositions.

Departure Course and Distance.-The course and distance a ship would have made from a known spot to arrive at the place whence she departs on a voyage. The ship's actual position is only known by her bearing and distance from a known landmark. The latitude and longitude of this landmark are given; and thence, by supposing the ship to have sailed, on a course opposite to the hearing of the object, through the distance between that object and her starting point, the latitude and longitude of this latter place is also found. On commencing a voyage we thus get a determinate starting-point from whence to reckon our subsequent courses and distances. In correcting the departure course for the deviation of the compass, we must bear in mind that the ship's head (on which the amount of deviation depends) is not necessarily in the same direction with the course. She may be "lying to," or riding anchor, and swinging to any point of the compass when the bear

Departure, Taking a. The process of determining place of the ship preparatory to departing on a royage. This is is taken.

by referring it to some other position of known latitude and longitude.

A fixed and conspicuous object is determined on, and the direction in which the ship lies from this, and her distance from it, are found.

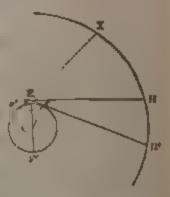

I. Without the help of the chart.—1. The direction the ship holds with reference to the object is furnished at once by taking with the compass a bearing of the object from the ship. 2. To determine the distance—(1) When not very great, the distance may be estimated with the eye with sufficient accuracy. (2) When the ship's path has across the line of direction of the object, the distance may be found from two bearings of the object and the run of the ship in the interval of time between taking them. (3) Sometimes the distance may be measured by the velocity of sound. (4) When the object of departure is the summit of high land of known elevation, its distance may be easily found, either when the object is seen on the sea horizon or above it. In case the slevation of such land is not known, the distance may be found, while standing directly towards or from it, by means of two altitudes and the run in the interval of time between observing them.

Mith a chart a departure may be taken by any of the following methods:—(1) By cross hearings. The bearings of two points of land (with a difference of bearing of as nearly 90" as possible) are observed, and the lines of bearing laid down on the chart. Their intersection gives the place of the ship. (2) By two angles between three objects; a method used when considerable accuracy is required as in recovering a lost anchor, verifying soundings, etc. (3) By th: coundings; when the depth of water is not very great, and varies sensibly with the distance of the object set. (4) The line of bearing of a single object may be combined with another line which crosses it nearly at right angles, and on which it is also known that the ship

lies. Such a line also may be obtained by Sumner's method. If the latitude of a ship is known when the object bears N. and S., her position is determined. or, if her longitude is to be depended on when the object bears E. and W., or nearly so, her position may be laid down. Combinations of this kind would be used in cases when the Bearing of one object only (as a low point of land) can be taken and there is no other means of determining the distance.

Depression, Angle of.—When a spectator is looking down upon an object, the angle of depression is the angle through which the object appears depressed below the horizontal plane drawn through his eye. We speak of the "Angle of Depression" or the "Angle of Elevation," according to the relative position of the spectator and the object.

Depression or Dip of the Sea-Horizon.—The angle through which the sea-horizon is depressed in consequence of the elevation of the eye of the spectator above the surface of the earth. The visible horizon may be regarded as the intersection with the celestial concave of a cone whose vertex is the eye, and which touches the earth's surface in a small

circle—the sea-horizon [Horizon]. If the eye be situated actually on the surface, this cone becomes a plane, and the sea horizon a point; and the greater the elevation of the eye, the greater evidently will be the extent of the sea horizon. Thus, as the eye becomes elevated the sea horizon becomes "depressed" in proportion. Let E be the place of the spectator's eye at an elevation EF above the earth's surface, I being vertically under him. Then E is the centre of the

celestial concave. Draw the horizontal EH through E, meeting the celestial concave in H; and through E also draw the tangent E-H', meeting the celestial concave in H'. Then the angle HEH' is the depression of the horizon for the height FE. To show how the dip is calculated -If c be the elevation of E (= FE), and R the radius of the earth (= Cs); then dip = HEH' = 90° - sEC - ECs.

Tan. dip = tan. 
$$EC_8 = \frac{E_7}{C_8} = (by Euc. m. 36) \frac{\sqrt{EF' \times EF'}}{C_8} = \frac{\sqrt{2e \cdot R + e^2}}{R} = \sqrt{\frac{2}{R}}$$
 nearly. A table called "Dip

of the Sea-Horizon" is inserted in all nautical tables, calculated generally up to 300 feet elevation, that being the limit within which all observations are taken at sea. An accidental relation furnishes us with an easily remembered rule for finding it approximately.—The dip in minutes is the square root of the height in feet. The dip is one of the "corrections" that has to be applied to the observed altitude of heavenly bodies taken at sea. The observer on the deck of the ship brings the image of the body (as X) down to his visible horizon. Thus the observed altitude (as H X) is too great, and has to be diminished by the dip (HH') to obtain what it would have been if observed from the surface of the earth (HX). The dip gives the distance of the visible horizon, for the arc Fs is measured by the angle ECs = 90°—CEs = HEH'.

Depression or Dip of a Shore-Horizon.—Sometimes, when the distant sea-horizon is hidden by the intervention of land, an altitude has to be observed from the water-line on the beach. The distance of this "shore horizon" may be estimated nearly; it is always less than the distance of the sea-horizon. The dip for the

shore-horizon is greater than the dip for the sea-horizon. It is given in a table of which the arguments are "the height of the eye" and "the distance of the shore."

Depression or Dip. Apparent and True. -The amount of the dip is affected by refraction, and according as the effect of refraction is not or is allowed for, the dip is called apparent or true. Refraction raises the sea-horizon, but the amount of the consequent correction cannot very accurately be determined. Imman gives it as about '08 of the dip, independently of this correction. apparent place of the sea-horizon is not only subject to inequalities depending upon particular states of the atmosphere, but it also varies with the relative temperatures of the sea and air. When the sea is warmer than the air the apparent dip given in the table is too small, in consequence of the sea-horizon being under these circumstances below its mean place; when the sea is colder than the air the contrary is the case In finding, with the sextant, the altitude of any body when it is above 60°, the uncertainty to which the dip is hable may be eliminated by observing the altitude from the two opposite points of the horizon.

Deviation (L. de, "from"; via, "way"). Turning saide from the way or the right line. This term is used for the deflection of the compass needle from the magnetic meridian caused by the attraction of the iron on board the ship.—[Compass] It is sometimes qualified as the "Local Deviation." Such qualification would be appropriate and necessary if there were a deviation, resulting from any other cause, from which to distinguish it. Raper, who invariably uses it, recommends that the simple term "Deviation" should be

used rather in a generic sense implying the introduction of the term Magnetic Deviation. Still, however, he retains the common word "Variation," but always qualifies it as "Magnetic Variation."

It is now generally agreed to confine the term "Deviation of the Compass" exclusively to the error caused by the attraction of the iron in the ship, whether employed in her construction, in her equipment, or in her cargo. For the three sources of compass errors, see Compass Errors.

Diametral Plane of a Sphere.—A plane passing through its centre and dividing it into hemispheres.

Difference of Latitude -The difference of latitude of two places on the earth's surface is the arc of a meridian intercepted between their parallels of latitude. Hence the difference of latitude of a ship for any period of a voyage is the distance she makes good in a north or south direction. This is called also her " Northing " or "Southing," these names being indicated by their initials, N. and S. When the two places are on the same side of the equator, the difference of latitude is found by subtracting the less from the greater; when they are on the opposite sides of the equator the difference of latitude is the numerical sum of their latitudes. If, however, the latitudes reckoned north are called positive, and those reckoned south negative, then the difference of latitude is always the algebraic difference of the latitudes. In plane sailing the above term is sufficient in itself, but in spherical sailing the introduction of the Meridional Difference of Latitude makes it necessary to make use also of the term " True Difference of Latitude," It is connected. with the distance and course by the relation-True diff. lat. = dist x coe course. - See Rhumb Sailing, Fundamental Definitions, and Fundamental Propositions.

Difference of Longitude. -The difference of longitude of two places on the earth a surface is the arc of the equator included between their meridians, or, which is the same thing, the corresponding angle at the pole. If longitudes are reckoned from the first meridian both ways eastward and westward, then, when the two places are both in east or both in west longitude, the difference of longitude is found by subtracting the less from the greater; when one of the places is in east and the other in west longitude, the difference of longitude is the numerical sum of their longitudes, except when the sum is greater than 180°, in which case it must be subtracted from 360 — It is, however, advisable to reckon longitudes in one direction, westward, completely round the circumference, and then the difference of longitude is always found by subtracting the less from the greater, and taking the remainder from 360° in cases. where this remainder is greater than 180°. Problems involving the difference of longitude can only be solved by the methods of spherical sailing. We have the relation,

Diff long . Mer. diff. lat. x tan. course;

and in the particular case of parallel sailing,

Duff. long = dist. × sec. lat. -See Rhumb Sailing, Fundamental Definitions,

Dip .- In taking the meridian altitude of a heavenly body whe Fundamental Propositions. it ceases to rise, it image, as seen through the telescope of a sextant no longer separates from the horizon, but begins to everlap it.

Dip or Inclination of the Needle.-The angle which body is then said to "dip" magnetized needle, when free to move vertically, makes with horizental. The common term Dip is preferred by some to

eccentific Inclination, because it directs the mind to that pole of the needle which is below the horizon. The dip, like the variation, undergoes a cycle of change, and has also diminal oscillations. Its present value at London is about 67". The dip is of importance to the navigator, as it appears to regulate the local deviation of the compass. It also renders necessary an adjustment to secure the horizontality of the compass card.

Tan, dip - 2 tan, mag, lat

## Dip of the Horizon. - See Depression.

Direction. - It is important in navigation to note the manner in which direction is conventionally described. The direction of the wind is named after the point of the compass from which it blows. whereas the direction of a current, stream, or talewave is named after the point of the compass towards which it sets or is propagate! The reason of this is, that the importance of the wind depends in a great measure upon what it brings us storm or rout, cold or heat , and also, the direction of the wind being apparent, it can be made available in steering the course required, and nearer the eye of the seeman is directed to wandward. On the contrary, the direction of the current is generally only found afterwards from its effects upon the position of the slap, carrying it towards fac point to which it is setting - the mind of the section is, therefore, then ? to the direction in which he may be un observedy drifting to direct. and, also, it is from the point t wirds which be may have mitted that I a has vibacquently to make a low mee and trackly his course, A melt is named after the point of the compass, mand the waves proceed, like the wind that produces them, This is, however

sometimes expressly mentioned: c. q. "Swell from S.E." instead of "South-easterly swell." The "land-breeze" and "sea-breeze" blow respectively from the land and from the sea.

Distance.—There are no fewer than four different senses in which seamen will find this word used, viz:—(1) the length of the track which a ship makes in sailing from one place to another without changing her course; (2) the length of the shortest route between two places; (3) the angle subtended at the eye between two objects; (4) the difference in time between the meridians of two places. These differences in the use of the word, are recognised in the following definite terms. (1) Bliamb distance, (2) Great Circle Distance, (3) Angular Distance, (4) Chronometric Distance.

"Distance" -In navigation this term is used in a technical sense. The "distance" between two places is the arc of the rhumb line joining them expressed in na it.cal indes. It is the length of the shops track when she sails on a constant course from the place of her department to the place of her destination. This is always the sense in which the world "distance" is understood by the navigator, when standing alone. It is not the shortest distance; for just as on shore we speak of the distance we should have to walk from one place to the other, and not the distance as the crow flies, so on the sea we speak of the distance which we in practice sail over. With a view of guarding against ambiguity the term. "Nauteal Distance" has been introduced. On a Mercater's Chart the thimb is represented by a straight line, but it must be borne in used that equal parts of any such line do not represent equal distances on the earth's surface.

The distance is connected with other elements by the relations :-

Dist. = departure x cosec, course;

Dist. = true diff. lat. x see course.

In the particular case of parallel sailing,

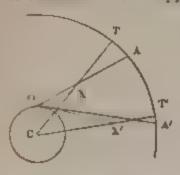

Dist. - diff. long. x cos. lat.

—See Rhumb Sailing. Fundamental Definitions, and Fundamental Propositions.

Distance, Shortest, .- The shortest distance between two places on the earth a surface is the intercepted are of the great circle passing through them. When we speak of the distance between two points on a plane, we mean the shortest distance, and so, in a strictly geometrical sense, on the surface of a sphere the distance would mean the shortest distance. The term distance, however, being used by the navigator in a technical sense for the arc of the rhumb track between two places, when the arc of the great circle is to be indicated. the word should always be qualified as the shortest distance. In great-circle sailing the shortest distance is the track approximated to; and on a chart on the central projection this track is represented by a straight line; but it must be borne in mind that equal parts of any such line do not represent equal distances on the earth's surface. In great circle sailing the shortest distance is found by the solution of a spherical triangle of which two index and the included angle are given, from the known latitudes and longitudes of the two places, Ree Great Circle.

Distance of Two Heavenly Bodies.—This is to be understood not as the absolute linear distance between the two bodies, but their angular distance from each other as seen from a certain point, measured by the arc of the great-circle joining their projections on the celestial concave. The angular distance is taken

by a navigator situated at any place on the earth's surface with a sextant, and the uncorrected result of such an observation is called the Observed Distance. This being cleared of "index error" and (if limbs of the bodies are observed) of "semidiameters," the observed is reduced to the Apparent Distance. Again, for comparison and

computation, all elements have to be cleared of the effects of "refraction" and "parallax"—i.r reduced to what they would be if taken by an observer looking through a uniform medium from the centre of the earth. The apparent distance is thus reduced to the True Distance. The two may, therefore, be thus distinguished. The apparent distance of two

heavenly bodies is their angular distance as viewed through the atmosphere by a spectator on the earth's surface; the true distance is their angular distance cone and to be viewed through a uniform medium from the earth's centre. Thus, let A and T be the apparent and the places of the moon when at X; A' and I the apparent and true places of the moon when at X. Then AA is it e apparent distance, and TT the true his time between these two positions.

Distance, Meridian. The defence in time between the mend and of two place. See Longitude, Difference of, in Time.

Double Altitude.—A combination of two altitudes for the solution of the same problem, as in finding the latitude or rating a chronometer. It is usual, however, to restrict the term Pouble A't to to the rightness method of finding latitude by two altitudes of a body, or of two podes, and to distinguish as an "Equal A titude" those for rating chronometer. See Altitude.

Double Chronometer -A name sometimes given to a particular case of finding position by Sumner's method, when both bodies happen to be sufficiently far from the meridian.

Draco (L. "The Dragon") — A winding constellation, whecommencing from between Ursa Major and Ursa Minor, extends to Lyra. The two principal stars, γ and β, form a conspictious part situated nearly on the line joining a Lyrae and a Ursae Majoris; the line which joins a Cyania. If Brotis also passing near them. γ Draconis, also called Ra i and is the nearest one to Lyra; in its diurnal course it passes over London; and if a line be drawn from it to Polaris, the pole of the ecliptic will be near this line, at about the same distance from γ Draconis as that star is from Lyra. This star is of historic interest, as a change in its polar distance attracted Brailley's attention and led to the discovery of aberration. Mag. 24: NA, 1896, RA 175 54π; Pec. + 51° 30° β Draconis, mag. 30 RA 175 23m, Tree + 52° 23.

Drift of a Current —The distance through which the current flows in a given time. Drift = time < rate. See Current and Race.

Drift Current. -A surface current produced by the action of the wind.

Dubhe The Arabic name for the bright star a Ursu Majoris.

—See Ursa Major.

Dygogram "Force and Angle Diagram." (A contraction for "Dynamogonio-grain"; δωναμικ "force," γωνία "angle," γράμμα "delineation from γράφω "to grave.') A geometrical construction

to represent the amount and direction of the forces which act on the compass needle. There are several distinct forms, each with its peculiar advantages; they will be found described in the "Admiralty Manual for the Deviation of the Compass."

Earth, The -Symbol 5 or &. The planet of the solar system third in order from the sun, its orbit being between those of Venus Distance from the sun in miles: mean 92,965,000; greatest 94,524,000, least 91,406,000. Time of revolution round the sun in mean solar days 365-2563. Time of rotation on axis 23h 56m 4s . and Mars. Inclination of equator to orbit 23° 27' 24".

Earth, Figure of. -The arguments which appeal to the experience of seamen are sufficient to indicate the Earth's general

- (1). That it is not an unlimited surface, but a body solated in space, of definite demensions, is shown by stars being seen to disappear below the horizon on one side and to reappear the next night, on the form : other. And by keeping in a generally easterly or westerly direction, though on various courses, the earth is constantly being circum-
  - (2) The uniform circular appearance of the sea-horizon proves the the earth is spherical. Beyond this circle objects are hidden by the navigated. intervening portion of the curved surface, but as they approach nearer they rise to view and become more and more visible, the masts and slender spars being detected before the massive half seen. This conclusion is confirmed by other phenomena. who keeps watch by night, oftener than other men observes le colipses: these are caused by the Moon passing through the share of the Earth, and no one has ever seen the dark outlin on the E then circular, the shadow namely which a sphere would

- (3) But accurate measurements of arcs of the meridian show that the Earth is not a perfect sphere. A meridian as it approaches the pole is found not to have so great a curvature as it has near the equator, which proves that the Earth is somewhat flattened in its polar regions, bulging out in a corresponding degree in the equatorial regions. Such a figure is called an Oblate Spheroid. A symmetrical one would be generated by the revolution of an ellipse about its minor axis, and is hence called an Ellipsoid of Revolution. The conclusion derived from measurements of arcs of meridians is confirmed by pendulum observations and deductions from the motion of the Moon.
- (4) But finally, from a survey of grodetical results all over the world it is found that different meridians possess different amounts of curvature, so that the equator is itself an ellipse instead of being a circle, and that the shape of the earth is an Ellipsoil of three unequal axes.

Earth, Magnitude of.—The dimensions of the terres'rial spheroid, as deduced by different authorities, vary with the more extended and accurated data available, We give two:—

## Diameters in feet

Longest equatorial. Shortest equatorial. Po ar,

SIR JOHN HERSCHEL,

(Astronomy 7th edition) 41,852,864 41,843,096 41,707,796

COLONEL A. R. CLARK,

(Encycl Brit, 9th edit. 1877) 41,852,700 41,839,944 41,706.858.

Lamiting the figure to an ellipsoid of revolution Colonel Carks gives the result equivalent to

Equatorial diameter, 41,852,124 feet or 7926 5 miles. Polar diameter, 41,710,242 ,, 7899 7 ...

the ratio of the one to the other being 203 98 to 294 98, and the one exceeding the other by about 26 8 miles.

Professor J. Norman Lockyer (1894) gives the figures as 41,852,404 and 41,709 790, the difference being 27 miles.

Until lately the thickness of the protuberant ring was generally taken to be  $_{3}^{1}_{6}$  of the equatorial radius. Pendulum experiments give an ellipticity of  $_{3}^{1}_{5}^{1}_{5}^{1}_{5}$ , and that deduced from the motion of the Moon who. The fraction generally adopted at present is  $_{3}^{1}_{2}$ . Considering the linth as a sphere, its circumference may be taken in round numbers to be 25 000 miles, and its diameter 8,000 miles. The diameter is about the 100th part that of the Sun.

East Point of the Horizon —The cost is the cardinal point on that side of the horizon where the heavenly holices rise. The East and West Points are the points in which the prime vertical intersects the borizon, the equinoctial also passing through them; and they are the original from which amplitudes are reckoned. They are the poles of the celestial meridian.

Easting -The distance expressed in nautical nules a slop makes good in an east direction; it is her departure when sailing eastward Opposed to Westing.

Eclipse (Gk. & Accepts, from & Accepter, "to leave out," "to fa' to away," "disappear"), -- The phenomenon of a celestral body disappearing from view in whole or in part, in consequence other of its passi

through the shadow of another body, or from the spectator passing through the shadow of an intervening body. The sum (88), the source of light in our system, is much larger than any of its opaque attendant planets. Every planet

primary and secondary (as PP'), thus casts a control shadow into space (PPU) called the *Umbra*, within which a spectator can see no part of the sun's disc. Enveloping the ninhra is a portion of another conical space (PSP'B) called the *Penumbra*, where if a spectator be attuated be can see a portion only of the sun's disc, and receive only partial sunshine, and less and less the further he enters from the exterior borders of this cone.

- 1. Let us consider the cases where the celipse of a body takes place by its passing through the shadow of another body, presenting an appearance independent of the position of the spectator.
- I. Linear Eclipses. A lunar eclipse takes place when the moon is in opposition, or on the opposite side of the earth from the sun (and whee, therefore, it is full moon), provided she is at the same time very near one of her nodes, or the points where her orbit crosses the plane of the celiptic. If the full moon is in the node, it will also be in the axis of the earth's shadow, and the eclipse will be central, possibly continuing for two hours, as the breadth of the shadow where the moon crosses it is about 23 the moon's diameter; when the full moon is so near the node as to be wholly immersed in the shadow, the eclipse will be total; and when only a part of the disc is immersed, the colipse will be partial.
- 2. Jupiter and his Satelli'er.—Instead of the earth and moon, we may contemplate any other planet that has a satellite, and in doing so, we shall notice two different kinds of colipses. The case of Jupiter is the most important, (1) The satellite is eclipsed in the shadow of the planet, such phenomenon being to a spectator on the surface of Jupiter a lunar colipse. (2) We observe also the shadow of the satellite passing over the disc of the planet. By a spectator on a

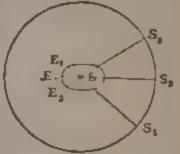

portion of the surface of Jupiter in such a case, a solar cohpae would be experienced, but as viewed from the earth, such a phenomenon is described as a transit of the shadow of the satellite.

II. The second case is where a body is eclipsed by the spectator passing through the shadow of the intervening body, the appearance being different according to the position of the spectator. This occurs in Solar Eclipses. When the moon is in conjunction i.e. in the same part of the heavens with the sun (and when, therefore, it is new moon) -the intersection of the moon's conteal shadow with the earth's surface produces a black spot which sweeps over the illuminated hemisphere of the earth from west to east, and resembles in its effects a cloud carried by a west wind which bides the sun from the places nearly below it To places over which the umbra passes, there will be a total eclipse; those places which the penumbra reaches will experience a partial eclipse. In case the umbra of the moon does not extend as far as the earth -or, in other words, when the moon's apparent diameter is less than that of the sun-a spectator below the centre of the umbra will see an annular coupse, the dark disc of the moon being surrounded by a luminous "ring" of the sun's disc.

There is another class of phenomena analogous to echpses, and which are sometimes included in the term, These are Occultations. and Transits. (1) An Occuttation occurs whom a body is hidden from view by an apparently larger body intervening between it and the spectator. Thus the moon interposes and causes occultations of fixed aters and planets; the planets hide from view their satellites, e.g. Jupiter Vecultations furnish a mode of obtaining Longitude. See Longitude. (2) A Traumt occurs when a small body passes acres the disc of a larger one. Thus, we have transits of the inferplanets, Mercury and Venus, across the face of the sun; and of the character strictly speaking is an annular eclipse of the sun by the moon. We have also transits of Jupiter's satellites across his disc. Particulars of these phenomena are given in the "Nautical Almanac."

Ecliptic (Gk. & exercise, "pertaining to an college"), so called because an eclipse of the moon is only possible when she is in or near the celeptic.—The path which the sun appears to describe annually in the heavens, round the earth as centre, from west to east, in consequence of the revolution of the earth in her orbit round the sun in the same direction. The ecliptic is a great circle of the celestial concave, though the earth's actual orbit is an ellipse. To explain this: Let the figure represent the sun (S<sub>i</sub> in one of the foci of the elliptical orbit of the earth (E<sub>1</sub>, E<sub>2</sub>, E<sub>4</sub>, etc.) and a section of the celestial concave by the plane of this orbit indefinitely extended (S<sub>1</sub>, S<sub>2</sub>, S<sub>3</sub>, etc.) To a spectator situated on the earth at E, the sun will appear to be projected on the celestial concave at S<sub>1</sub>, as the earth moves on to

E<sub>2</sub>, the sun will appear to move on to S<sub>1</sub>, and when the earth arrives at F<sub>1</sub> the sun will be at S<sub>1</sub>; and so on until the earth, having made a complete revolution, arrives again at E<sub>1</sub>, when the sun also, after a complete apparent revolution, will be seen again at S<sub>1</sub>. The ecliptic is the natural equator of the heavens, and is the

primitive circle in one of the systems of co-ordinates for defining points of the celestial concave and indicating their positions relatively to each other, the co-ordinates being longitude and latitude. The celiptic is divided into twelve parts called "signs," each containing 30', and receiving their maines from constellations which were attracted in them at the time the names were given. These divisions commence from the vernal equinoctial point, or first point of the signance.

Elevation, Angle of —When a spectator is looking upwards at an object, as the top of a column the angle of elevation is the angle through which the object appears elevated above the horizontal plane passing through his eye. When he is looking at an object situated below the same horizontal plane, as at the reflection of the top of the column in a pool of water we speak of the angle formed in the same manner as the Angle of Depression.

Ellipse (Gk Accepts, "a falling short of"). -For explanation of the derivation of the word see Conic Sections. The ellipse is a figure of great importance to the nautical student. Its form, in a general sense, is oval. Its exact form is given by this property: Within it are two points called foci, such that the sum of the distances of any point in the c reumference from them is constant. Setting aside the reciprocal attraction of the earth on the sum, and the perturbations caused by the attractions of the other bodies of the aystem, the earth revolves in an ellipse round the sum in one of the foci. And this is the same for the orbits of the other planets. Again the form of a meridian of the earth is an ellipse

Emersion (i. emergere, "to come out").—The termination of an occurtation, or the moment when the occulted body respicars from behind the nearer one.

Epact (Gk. ἐπάγειν, "to add in) —The number indicating the days and parts of a day "to be added" to the inner year of two lunar months to make it up to the solar year. This number a consequently the moon's age at the commencement of the calenger. A mean lunation is 204 124 44 n; the moon therefore des. In in 365 days twelve complete lunations, and 104 15h of the thirtee hence on each 1st January its age is 104 15h, on the average, if

than on the preceding let January, and 114 15h if the preceding year was a leap year. The Epact for the Year is the moon's age on let January Besides this there is what is distinguished as the Epact for the Month, which is the moon's age on the first day of the mouth, supposing the moon to change on 1st January at no. n. These are used in questions relating to the tides, and are given in Nautical Tables.

Ephemeris—plural, Ephemerides (Gk. ¿φημερίς, "a diary", from em, prefix indicating sequence and repetition, and ἡμέρος, "a day") — An Astronomical Almanac is so called. In such an almanac are registered the daily positions of the sun, moon, and planets, with similar useful information respecting the other heavenly bodies; also phenomena depending upon these as the tides. The value of all the various elements is not tabulated for every day at noon, but at such intervals as the nature of the several elements points out as most advantageous in each case. The term is also applied to the different tables contained in the almanac; thus the table which gives the position of the sun for every day is called "The Ephemeris of the San," so we have "The Ephemeris of Mars," etc. The full title of the "Nautical Almanac" is "The Nautical Almanac and Astronomical Ephemeris," and the similar work used by the Germans is "The Ephemeris of Berlin."

Equal Altitudes. -Two equal altitudes of a heavenly body observed while it is rising on the east side and falling on the west side of the meridian. - See under Altitudes.

Equation (L. aquetto, "a making equal") In astronomy the quantity to be ad led to a value of an element estimated in one way, to obtain its equivalent in another form which is required. Thus we have Equation of Equal Attitudes, Equation of Time, etc.

Equation of Equal Altitudes. -- See under Altitudes.

Equation of Second Differences. -- See under Second
Differences.

Equation of Time. - The difference between apparent and mean time. It is measured by the angle at the pole of the heavens between two hour-circles passing, the one through the apparent sun's centre, the other through the mean sun. The equation of time is so called because it enables us to reduce apparent to mean, or mean to apparent time. In consequence of the motion of the sun in the colpite being variable, and the colpite not being perpendicular to the axis of the earth's rotation, apparent time is variable [Mean Sun], and this fluctuation is considerable, amounting to upwards of half an hour -apparent noon sometimes taking place as much as 161m before mean noon, and at others as much 14jm after. These are the greatest values of the equation of time; it vanishes altogether four times in the year-this occurring about April 15, June 15, September 1 and December 24. It is calculated and inserted in the "Nautical Almanae" for every day in the year. On p. I. of each month, the equation of time given is that to be used in deducing mean from apparent time, that on p. II. is to be used in deducing apparent from mean time. The difference in the value of the two arises from the one being that at apportat and the other that at mean noon. may be separated by an interval of more than a quarter of an hour. the equation of time given in pp. I. and II. may differ by a quarter or the "Diff. for I hour 'given in the adjoining column.

Equation of Light.—A body is seen by the light which was conttol from it at some date antecedent to that at which the light enters the eye. The interval is what is required by the undulations.

to traverse the space between the body and the spectator. If the object is in motion, like the sun, moon and planets, this will cause a disturbance of its place in the celestial concave, which must be allowed for in reducing its apparent to its true place.

Equation, Personal, see under Personal.

Equator (L. aquare, "to divide into equal parts") : -

- 1. Terrestrial Equator.—That great circle of the earth whose plane is perpendicular to the axis of the earth, and consequently every point of which is equi-distant from the north or south poles. It divides the globe into the northern and southern hemispheres. The equator is the primitive circle in the system of co-ordinates used for defining the position of places on the earth's surface. Origin intersection of the equator by the first meridian; co-ordinates—longitude and latitude.
- 2. Celestial Equator. That great circle of the celestial concave whose plane is perpendicular to the axis of the heavens. It is the great circle in which the plane of the terrestrial equator, indefinitely extended, intersects the celestial concave. The celestial equator is also called the "Equinoctrial," and is the primitive circle in a system of co-ordinates used for defining the position of points on the celestial concave. Origin—first point of Aries; co-ordinates right assension and declination.

From a comparison of the above two definitions, the application of the same term "equator" to the two great orders of the earth and beavens under consideration seems appropriate, and possibly no ambiguity can occur in its use, even without the qualifying adjectives "terrestrial" and "celest al." But with students, the double use of the word often engenders a vagueness and erroneousness of conception

of the things indicated, and therefore the following points must be carefully borne in mind: (1) There is not generally that connection between the circles of the earth and those of the heavens which at first sight appears. The earth rotates, while the heavens are fixed; and thus the terrestrial equator also rotates in its own plane, while the celestial equator must be fixed, as the origin of co-ordinates for the heavens is a point in it. (2) Again, the ecliptic, and not the equinoctial, would appear to form the natural "equator" of the heavens, as is indicated by the name of the co-or hoates in the system of which it is the primitive—longitude and latitude. See Longitude and Latitude.

In consequence of these and other general considerations, some writers restrict the word Equator to signify the Terrestrial Equator, and use the term Equatorial when speaking of the Celestial Equator. This plan, if uniformly adopted, would be advantageous.

Equatorial Projection of the Sphere —A projection of the sphere, whether orthographic, stereographic, or central, in which the print tive plane, or plane of projection, coincides with or is parallel to the "equator."

Equiangular Spiral (L. oques, "equal"; angulas, "an augae". A spiral is a curve which continually rece les from the centre or pole while revolving about it, the equiangular spiral on the carth's surface is the spiral which cuts the meridians at a constant angle. It is also called the "Lex Icomic Carre," and the "Roumb Lim".

Equinoctial (L. aquas, "equal", nor, "night").—That great encle of the celestral concave whose plane is perpendicular to the axise of the historis; consequently, every point of it is equi-distant from the north and south poles. It divides the heavens into the northers. and southern hemispheres. The name is derived from the following phenomens at all the places on the earth's surface beneath this circle the nights are equal all the year round, being of the constant length of twelve hours - the sun setting at 6 P.M. and rising at 6 A.M.; and when the sun crosses the equinoctial as he does twice in the year, at the vernal and antumnal equinoxes—the nights are of equal length, all over the globe. The equinoctial is sometimes called the "Celevial Equator," as being the great circle of the celestral concave marked out by the plane of the terrestrial equator if indefinitely extended. It would be convenient if this compound term were altogether superseded by the supple word Equinochial, and the "tecrestrial equator" uniformly indicated by the simple word Equator. The equinoctial is the primitive circle in one of the systems of co-ordinates for defining posits on the celestral concave, and indicating their positions relatively to each other. Origin -vernal equinoctial point; co-ordinates -right ascension and declination.

Equinoctial Colure. The hour-circle which passes through the equinoctial points. In the polar co-ordinates for the celest al aphere, it is the initial position of the secondary circle. See Colures

Equinoctial Points.—The two points of the collection which it is intersected by the equinoctial. They are distinguished as the Vi not Equinoctial Point and the Autumnt Equinoctial Point, but are take generally called the First Point of Lives and the First Point of Lives, and they are represented as a symbolic 7 and as The was stellations of Aries and L. 19, 13 against now connected in position with them, give their notable the lives with the ecliptic, and the figure of the Balance (I. 1997) and the fere co to the equipolate of the day and night at the content of the rest of Aries is the

origin or zero point, from which right ascensions are reckoned on the equinoctial and longitudes on the ecliptic. The equinoctial points do not, however, preserve a constant place among the stars, but travel backwards along the ecliptic-i.e. from east to west, or contrary to the direction in which the sun appears to move in that circle. This retrogression is extremely small, amounting to 50-1" annually, so that a complete revolution would occupy 25,868 years. It is of great inconvenience to practical astronomers, as it renders obsolete, from time to time, their catalogues of the stars, which are referred to this shifting vernal equinoctial point as origin. Since the formation of the earliest catalogues on record the place of the first point of Aries has retrograded about 30°, altering to this extent the longitudes. The technical phrase for the phenomenon is the Precession of the Equinoxes, a term derived from the fact that the epoch of the equinox every year "precedes," or is earlier than it would have been but for the retrogression of the first point of Aries.

Equinoxes (L. equus, "equal"; nor, "night").—The two periods of the year, about 21st of March and the 22nd of September, when the sun, in his annual revolution in the ecliptic, crosses the equinoctial. At these times the days and nights are of equal length throughout the world—hence the term. The two equinoxes are distinguished as the Vernal Equinox and Autumnal Equinox; the former being that when the sun passes from the southern to the northern hemisphere, the season being "spring" in the northern hemisphere; the latter, when the sun passes from the northern to the southern hemisphere, the season being "autumn" in the northern hemisphere. These terms are relative; for what are the vernal and autumnal equinoxes for the northern, are respectively the autumnal and vernal equinoxes for the southern hemisphere. In cases

where there is any danger of ambiguity or confusion, we may add the qualifying adjectives "northern" or "southern," as the case may be; thus, one date would be called the Northern Vernal Equinox or the Southern Autumnal Equinox, and the other the Northern Autumnal Equinox or the Southern Vernal Equinox. It is convenient to restrict (as we have done) the term Equinox to indicate a date or epoch of time; and to use the expression, Equinoctial Point, when we want to refer to a position or place in the ecliptic. Similarly for Solstice and Solstitial Point.

**Eridanus** (The river *Eridanus*, the Po).—A winding constellation in the southern hemisphere, containing one star of the first magnitude a *Eridani*. This star, called also *Achernar*, may be found by bisecting the line joining Fomalhaut and Canopus. Mag 1 0; N.A. 1896, R.A. 1h 34m, Dec.  $-57^{\circ}$  46'.

Errors of Instruments.—Under this head are classed sources of instrumental error which do not arise from essential imperfections, or for which there is no convenient or advisable means of adjustment. They are acknowledged, determined by experiment and allowed for, or else eliminated by adopting certain methods of observing.—See Instruments; Imperfections, Adjustments, Errors.

Hetablishment of the Port.—Synonymous with "Apparent Time of Change Tide," or, more correctly, "Apparent Time of Syzygy Tide." The time of high-water at full and change of the moon, at the given port, reckoned from apparent noon. It is the actual time of high-water when the moon passes the meridian at the same time as the sun; or the interval between the time of transit of the moon and the time of high-water on full or change days. The word "establishment" expresses that this time is taken as a standard.

quantity, "port" being added because it is generally of importance to calculate the time of the tide for ports only. Compare the German term "Hafenzeit," "harbour time." Whewell distinguishes between the Vulgar Establishment and the Corrected Establishment. The vulgar establishment may be determined roughly by observation on the day of full or change. The corrected establishment is the interval between the time of the moon's transit and the time of the tide, not on the day of syzygy, but corresponding to the day of syzygy; it may be determined by observing the intervals of the times of the moon's transit and the times of the moon's transit and the times of the moon's transit and the times of the tide every day for a semi-lunation, and taking the mean of them.—See under Tide.

F.

f.—Of the letters used to register the state of the weather in the log-book, f indicates " Fog;" f " Thick Fog."

Fathom (Sax. fethem). - Measure of length, six feet. Soundings are reckoned in fathoms.

Field of View.—The area within which objects are visible through a telescope or microscope when the instrument is adjusted to focus.

First Meridian.—The conventional meridian whence longitude is reckoned. In the early days of navigation, before the time of Columbus, it was not known that the direction of the compass needle goes through a cycle of change at any given place. At most places its direction deviates from that of the meridian; but it was observed, at the beginning of the sixteenth century, that it coincided with the meridian at the Isle of Ferro, one of the Canaries. This meridian was therefore fixed upon by the old geographers and navigators as the

first meridian. Upon the discovery, however, of the erroneous nature of their assumption, this method has been relinquished, and now different nations in general use severally the meridian of their principal observatory as their first meridian, Thus, English astronomers and geographers consider the meridian of Green wich the first meridian, the French that of Paris, and the Germans that of Berlin. The following are the longitudes of the most important foreign origins, reckoned from the meridian of Greenwich westward: Ferro, 17° 58'; Paris, 357° 39' 38"; Berlin, 346° 28'. In taking up a chart it is necessary to observe what meridian longitude is reckoned from.

First Point of Aries (L. Aries, "The Ram").—The "Vernal Equinoctial Point" is so called as being the commencement of the sign of the ecliptic of the same name; it is also represented by the symbol of that sign  $\tau$ .—See Equinoctial Points.

First Point of Cancer.—(L. Cancer, "The Chab").—The Summer Solsticial Point" is so called as being the commencement of the sign of the ecliptic of the same name; it is also represented by the symbol of that sign 2.—See Solstitial Points.

First Point of Capricorn (L. Capricornus, "The Goat").—The "Winter Solstitial Point" is so called as being the commencement of the sign of the ecliptic of the same name; it is also represented by the symbol of that sign &.—See Solstitial Points.

First Point of Libra (L. Libra, "The Balance").—The "Autumnal Equinoctial Point" is so called as being the commencement of the sign of the ecliptic of the same name it is also represented by the symbol of that sign  $\triangle$ .—See Equinoctial Points.

Fixed Stars.—See Stars.

Fog. -When an altitude of the sun or moon is wanted, a navigator is often disappointed by finding the horizon obscured, or the body itself shrouded in a mist or fog. If the sea-horizon, as seen from the deck, is thus unavailable, a new horizon may often be obtained by descending the ship's side, or from a boat. When the sun or moon are so indistinctly visible that the limbs cannot be distinguished, the hazy disc should be bisected upon the horizon.

Fomalhaut.—The proper name for the bright star a Piecis Australia.—See Placia Australia.

Fore-staff.—An ancient instrument for taking altitudes and distances at sea, and so called from the observer fronting the object; when using the back-staff his back was turned to the object.—See Gross-staff.

Frigid Zones (L. frigidus, "cold"). The two zones of the earth cut off by the polar circles. They are distinguished as the North Frigid Zone and the South Frigid Zone; the former being that in the centre of which the north pole is situated, and which is bounded by the arctic circle (about 66° 32½ N.); the latter that in the centre of which the south pole is situated, and which is bounded by the antarctic circle (about 66° 32½ S.). Reckoning from the pole to the polar circle, the breadth of each of the frigid zones is about 23° 27°. Within them, during one portion of the year (longer or shorter, according to the distance from the pole) the sun does not dip below the horizon, and during another corresponding period he does not rise above it, in the diurnal revolution. In consequence of the sun's rays striking the surface in these regions very obliquely, the temperature is exceedingly low, and hence their name — See Zones.

G.

g.-Of the letters used to register the state of the weather in the log-book, g indicates "Gloomy Dark Weather."

Galaxy. - See Milky-way.

Gale. -See Wind.

Gemma (L. "a jewel") —The proper name for the bright star Corona Boreais.—See Corona Boreais.

Gemini. Constellation of (L. "The Twins") —The third constellation of the zodiac, lying between Taurus and Cancer. The two principal stars are a Geminorum called Castor, and β Geminorum called Pollux. They may at once be found, as they form, with the two bright stars of Auriga, an arch round the head of Orion; as they rise, (spella is the uppermost star of the pair in Auriga, and Castor is the uppermost of the pair in Gemini, the name of the two beginning with the same letter. Or, again, a line joining Rigel and Retelgenx, and continued a little more than its own length, gives Pollux, and is also bisected by γ Geminorum, a Geminorum, (Castor) Mag. 1.6: N.A. 1896, R.A. 7h 28m, Dec. + 32° 7′. β Geminorum, (Pollux) Mag. 1.1: N.A. 1896, R.A. 7h 39m, Dec. + 28° 17′. γ Geminorum, Mag. 2.0; N.A. 1896, R.A. 6h 32m, Dec. + 16° 29′.

Gemini, Sign of.—The third sign of the couptic, including from 60° to 90° longitude. Owing to the precession of the equinoxes, the sign is at present in the constellation Taurus. The sun is in Gemini from about 21st of May to about 21st of June. Symbol II.

Geocentric (Gk. \gamma\hat{\eta}, "the earth"; \kappa\eta\taupor, "the centre"). Concentric with the earth; distinguished from Heliocentric, concentric with the sun. The geocentric place of an object is its position referred to the celestial concave, having the centre of the earth for its

centre; the heliocentric place is its position referred to a celestial concave concentric with the sun: the former supposes the spectator to be in the centre of the earth, the latter in the centre of the sun. Thus, we have geocentric longitudes and latitudes, and heliocentric longitudes and latitudes. In the Planetary Ephemerides of the "Nautical Almanac" the positions of the bodies are given geocentrically by right ascension and declination, heliocentrically by longitude and latitude.

Geodesy (Gk.  $\gamma \hat{\eta}$ , "the earth";  $\delta al\omega$ , "to divide).—That part of practical geometry which relates to the determination of the magnitude and figure of the earth or any given portion of its surface. It comprehends the trigonometrical operations necessary for measuring the lengths of degrees and constructing maps.

Geography (Gk.  $\gamma \hat{\eta}$ , "the earth";  $\gamma \rho d \phi \epsilon \nu$ , "to describe," "to grave"). The science which treats of the earth in its various aspects. It is divided into different branches: (1) Astronomical Geography, which regards the earth as one of the bodies of the universe, and investigates its form and dimensions; (2) Physical Geography, which takes cognizance of its natural productions; and (3) Political Geography, which describes the divisions appropriated by the various communities of men. The navigator is chiefly concerned with the first two branches, but all that is ancillary to the purposes of the seaman may be classed under the term Nautical Geography.

Geo-navigation (Gk.  $\gamma\hat{\eta}$ , "the earth").—A term which has been proposed for that branch of the science of navigation in which the place of a ship at sea is determined by referring it to some other spot on the surface of the earth. The other branch, in which the position of the ship is determined by finding the zenith of the place

from observations of the heavenly bodies, we distinguish the as Colonarigation. It has been customary to apply the term "Navigation," in a limited sense, to the former of these methods; but it properly indicates the entire science, and is used in that generic sense. Laxity in the use of scientific terms is very objectionable, and the confusion arising from the same term being used in different senses very inconvenient We therefore never use the word "Navigation" as a synonym of "Geo-navigation." Again, the term, "Plane Sailing" is sometimes loosely extended from its proper technical meaning to embrace the whole results of geo-navigation. The cause of this, perhaps, is, that apparently plane trigonometry only is used in the solution of its problems, it being overlooked that the construction of the table of meridional parts (of which use is made) involves the principle of the sphere. There are three methods in geo navigation : for the spot on the earth's surface to which we refer the place of the may be situed I some known landmark, (2) a determinate bottom, (3) a previously defined place of the ship. These will be found more fully noticed under Navigation.

Gibbous (L. gibbus, "protuberant"). -The phase of the moon when between half and full. The planets Mercury, Venus, and Mars present a similar appearance.

Gimbals or Gimbols, formerly Gimmals (L. gemelus "twin").

Pairs of brass hoops or rings which swing one within the other on diameters at right angles to each other, the pivots being on the inner surface of each successively larger hoop. Anything suspended in their centre retains a constant position relatively to the horizontal plane in whatever direction the framework is tilted; and hence this is the method used for hanging the mariner's compass in its place on board ship.

Glasses.—See Log-glass.

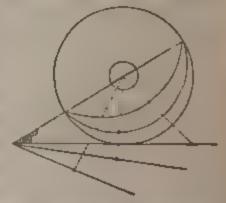

Globe (L. globus) —A term synonymous with the word, of Greek origin, "sphere." It is generally restricted, however, to mean the earth. Another special application of the term is to artificial spherical representations of the earth and the heavens.

Globular Sailing.—Antiquated term for Spherical Sailing.

G.M T.-The initials by which "Greenwich Mean Time" is referred to -See Time.

Gnomonic Projection of the Sphere (Gk. γνώμων, the

"atyle" or "index" of the sundial; from γεῶναι, "to mark").—The "Central Projection" is so called, as being that adapted for the construction of the dial. If the terrestrial sphere be imagined to be transparent, with an opaque rod for axis, then, in the diurnal revolution, this axis will throw a shadow corresponding to the hour-

projected on a tangent plane of the celestial sphere and a sun dial is formed.

Great Circle.—Great circles of the sphere are sections of its surface by planes which pass through its centre [Circles of the Sphere] The great circle is to the spherical surface what the straight line is to the plane. Just as the straight line is the shortest distance between two points on a plane, so is an arc of a great circle the shortest distance between the two points on the surface of a

sphere. A plane angle is formed by the meeting of two straight lines, a spherical angle is formed by the meeting of two great circles; a plane triangle is a figure contained by three straight lines, a spherical triangle is a figure contained by three arcs of great circles.

Great-Circle Sailing.—In great-circle sailing, the ship keeps on the great circle which passes through the place of departure and the place of destination. This is the shortest distance between the two places, and the ship steers for her port as if it were in sight. As the great circle, except in the cases of a meridian or the equator, does not make a constant angle with the meridians, in order to keep upon it a ship must be continually changing her course. This is practically impossible, and hence what is called Approximate Great-Circle Sailing is more or less adopted

in approximate Great Circle Sailing, several points on the arc of the great circle joining the place left and the place sought are fixed upon, and each of these made in a ccession by the ship sailing on the rhumb lines connecting them. The sum of the distances described on these several courses, if the points are not taken too far apart, will not differ much from the shortest distance. As the direct solution of the problem requires calculations, several plans have been devised at different times to facilitate the practice of great-circle sailing Amongst these may be mentioned Towson's "Linear Index and Tables." The Diagram called the "linear index" is followed by a table which gives, on inspection, all the courses on any given great circle for each 5' of difference of longitude. An instrument called "Sanby's Spherograph" is also designed to facilitate the practice of great circle sailing. But the method introduced by Hugh Godfray, Esq., M A., St. John's College, Cambridge, deserves special mention. A chart on the central projection exhibits the great circle as a straight

line, and thus it is seen at once whether the track between two given places is a practicable one; hence, also, we have by inspection the point of highest latitude. An accompanying diagram then gives the different courses, and the distance to be run in each, in order to keep within one-eighth of a point to the great circle. This chart and diagram" is fully described in the "Transactions of the Cambridge Philosophical Society," vol. x., part ii.

Godfray's Chart is a general one of the circumpolar region, and the point of tangency of the primitive plane is the adjacent pole of the earth, so that the meridians are represented as straight lines radiating from this point, and the parallels as concentric circles surrounding it. Restricted gnomonic charts have been recently constructed in America in which the point of tangency is the centre of the ocean which each chart depicts. The meridiansare thereforestraight lines not converging to this point and the parallels are area of conic at one. The great circle track between the places of depart ire and destination is the atraight line joining them. To find the direction and length of this line or the course and distance, a great-circle course diagram is engraved on the same sheet by which the course can be determined; and the distance can be measured either by means of differences of latitude or by the minutes of longitude contained in a particular portion of the track line. These charts are printed on a large scale on the back of the Pilot Charts of the different oceans issued monthly at the Hydrographic Office, Bureau of Navigation, Department of the Navy, Washington. The chart is not intended for use as a general sailing chart, but as a simple means of finding the course and distance at any time in great-circle sailing.

<sup>\*</sup> hagraved by the Hydrographic Office, Admiralty. Published by J. D. Potter, Poultry, London.

This system, thus officially adopted in the United States, will be found described by its author in a pamphlet which is accompanied by a specimen chart of the middle part of the North Atlantic Ocean. "Gnomonic Chart for use in Great-Circle and Windward Sailing with Simple Methods for Measuring Courses and Distances," by GUSTAVE HERRLE, C. E., Washington D.C., 1881.

Before Mercator's invention, great-circle sailing was commonly employed, and often in preference to rhumb sailing; but Mercator's method at once superseded it, and for the following reasons:—(1) The calculations were not so laborious, especially without the aid of logarithms, as in the great-circle method with only the direct solution; (2) The then uncertainty in the determination of a ship's longitude (chronometers not existing in their present perfection), which would be of least consequence in rhumb sailing, for a definite rhumb line and parallel of latitude of themselves determine the position; and (3) The Mercator's chart exhibits the track of the rhumb as a straight line—one great objection to great-circle sailing being the difficulty of ascertaining whether obstacles in the shape of land or rocks lie in the path. The improvement, however, in our means of navigation, and the extension of our commerce, especially to high latitudes, where the advantages of great-circle sailing are most conspicuous, have again called attention to it. Steamers may generally take advantage of the great circle, and sailing vessels must not overlook its principles, particularly in windward sailing. Great-circle sailing must not be regarded as a substitute for rhumb sailing, but its practical utility is most apparent when treated as an auxiliary to it.—See Nautical Magazine, 1847, p. 288.

It is of great use to be able to project the great circle on a Mercator's chart. The following method is a simple one:—Draw the

rhumb line between the two places; find the differences between the course thus obtained and each of the two terminal courses on the great circle found by calculation; on the polar side of the straight line joining the places set off the differences at each end, and from the same points draw perpendiculars to the lines thus obtained. The intersections of those pairs of perpendiculars, which make equal angles with the rhumb line, will be the centres of circles of which ares drawn between the two places will be the limits between which the required curve will lie. This curve can then be very approximately drawn by hand, taking care to make one extremity approach the sweep of that circular segment the angle of which corresponds to the great circle course at that place, and varying the curve more and more to the other extremity, so as to coincide ultimately with the sweep of the other segment, the angle of which represents the great circle course there.—See Naval Science, April, 1873, p. 190.

As great-circle sailing requires only the solution of a spherical triangle, it involves very little trouble each day to calculate the course on the great circle from the point arrived at to the port of destination, instead of trying to keep near to the great-circle passing through the original place of departure and the destination.

Indeed in a large majority of cases the course may be determined by inspection from the Burdwood and Davis Azimuth Tables now so generally used affont, without the necessity of any calculation whatever—See Nautical Magazine, July, 1895

Greek Alphabet.—The small letters of the Greek alphabet are used to distinguish the different stars of the constellations; thus the star Dubbe is a Ursa Majoris, Rigel is \$ Orionis. The navigator should not, therefore, be ignorant of these characters:—

```
a Alpha (a).
                   η Eta (ē).
                                    » Nu (n).
                                                    7 Tau (t).
                   B Theta (th).
                                    ξ Xi (x).
                                                    v Upsilon (u).
Beta (b).
y Gamma (g).
                   , Iôta (i).

                   д Мu (m)
                                   σ Sigma (a).
                                                    ω Oměga (č),
```

They are also used in algebraical expressions, especially for subsidiary angles.

Greenwich Date. -The time at Greenwich corresponding to any given time at another place. -See Date, Greenwich.

Greenwich Date Logarithm for the Moon.—The logarithm of 720 (the number of minutes in 12 hours), dimensibled by the logarithm of the number of minutes in any period less than 12 hours is called the "Greenwich Date Logarithm for the Moon" for that period. These are calculated for all periods up to 12h, at intervals of 1m, and form a table formerly used for finding the moon's right ascension and declination for any Greenwich date between those given in the "Nautical Almanac." This table is now superfluous, since the elements are given for every hour, with the variation per ten minutes—See Logarithms, Proportional.

Greenwich Date Logarithm for the Sun.—The logarithm of 1440 (the number of minutes in 24 hours), diminished by the logarithm of the number of minutes in any period less than 24 hours is called the "Greenwich Date Logarithm for the sun 'for that period. These are calculated for all periods up to 24h, at intervals of 1m, and form a table formerly used for finding the sun's right accession and declination for any Greenwich date between those given in the "Nautical Almanac." This table is now practically obsolete:

the best means of correcting these elements is supplied by their variation per hour, which is given for each day in the "Nautical Almauac." - See Logarithms, Proportional.

Gregorian Calendar, -The calendar as reconstituted by Gregory XIII. (Pontifex Maximus) - See Calendar.

Grus (L. "The Crane". -A constellation to the south of Piccis Australis; it has one bright star a Gruis, Mag. 1-9; N.A. 1896,

Gyration -(Gk. 7îpos, "round") -A vertical motion, or R.A. 22h 2m, Dec -47° 28'. rotation with a centripetal or centrifugal tendency. When there is a shift of wind, that shift is commonly towards the right in northern latitudes, and towards the left in southern latitudes. This has been named the Law of Gyration (das Drehungsgesetz, Dove).

h .-- Of the letters used to register the state of the weather in the log-book h indicates "Hail." Hail usually precedes storms of rain, but rarely, if ever, follows them. It is always accompanied by

Hack Watch .- A good watch with a second hand, used to taking observations to obviate the necessity of constantly moving the electric phenomens. chronometer -See Chronometer, Observations.

Hand-Lead .-- The instrument for sounding when passi through shallow water. -- See Sounding.

Heaving the Log.-Using the log to ascertain the rate

Heel (Sax hylden). To lean over. - A ship is said to heel chip is going. - See Log. the inclines laterally, that is, tends to lie over on her side.

Heeling Deviation.—The disturbance of the compass needle introduced by the heeling of the ship. It is commonly spoken of as the "heeling error," implying that it is an error to which the deviation (as determined when the compass is adjusted) is liable.—See Compass, Heeling Deviation.

Heliocentric (Gk. ήλιοι, "the sun"; κέντρον, "the centre").—
Concentric with the sun; distinguished from Geocentric, concentric
with the earth. The heliocentric place of a heavenly body is its
position referred to a celestial concave concentric with the sun. Thus
we have the Heliocentric Longitude and Heliocentric Latitude of a
planet.—See under Geocentric.

Hemisphere (Gk. prefix, ήμι, "half"=L. semi; σφαίρα, "a sphere")—Half the sphere. Every great circle of a sphere divides it into two hemispheres; thus the equator divides the terrestrial sphere into the northern and southern hemispheres.

Hercules.—A constellation to the south of Lyra and Draco, containing one bright star. This star and a Ophiuchi form a pair which may be found by their being the first bright stars in a line drawn southward from the pair in Draco, a Herculis being the nearest to the Great Bear. Mag. var. 3-1 to 3-9; N.A. 1896, R.A. 17h 10m, Dec. +14°31'.

Herrie's Gnomonic Chart.—See Great Circle Sailing.

High Water.—The phase of a tide when the water attains its highest level. Its opposite is Low Water.—See Tide.

Height of the Tide.—The difference in the level of high and low water. A preferable term for this is the "Range of the Tide.—See Tide.

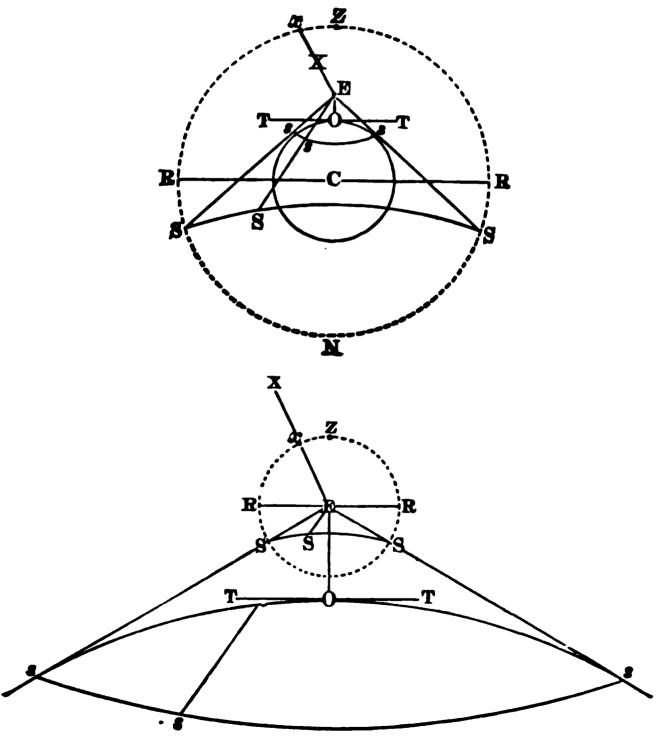

Height of a Wave. -The perpendicular rise of the vertex of the wave or "crest" above the lowest part of its depression or "hollow " \_See Wave.

## Horary Circles. -See Hour-Circles.

Horizon (Gk. opijus, "the boundary line"; from Spot, "a boundary") -The boundary circle in which the heavens and earth This boundary line not only thus appears to separate the surface of the earth from the celestial concave, but it divides each into two parts, the visible and invisible. The eye of a spectator is always practically more or less raised above the earth, so that his vision takes in more or less of the earth's surface, and more than a homisphere of the celestial concave. Thus let E be the place of a spectator's eye reused above the earth at O; it may be considered the vertex of a cone of visual rays, which are tangents to the earth's surface, marking out the terrestrial boundary of his vision w, and the celestral boundary of his vision SS, these two circles appearing coincident as the boundary of the earth and sky. Their position, besides varying with the elevation of the eye of the spectator, is also atill further lowered from the effects of refraction. Neglecting this the surface of the tangent-cone to the earth, having its vertex in the eye of the spectator raised above the surface of the earth, defines the Visible Hore-on for that elevation, both with respect to the earth with

(a) The small circle, in which the cone touches the earth, as the heavens. the "Terrestrial Visible Horizon," and the visible area which includes is but a small portion of the earth's surface. When spectator is surrounded by the open sea, this is called the Horizon" or " Offing."

(b) The cone again intersects the celestial concave in a small circle SSS, but so that more than a hemisphere of the heavens is within the spectator's field of view; this may be called the "Celestial Visible Horizon" for the given elevation.

The spectator always sees less than a hemisphere of the earth Osse, and always more than a homisphere of the heavens ZSSS. variable small circle like the sensible horizon SSS cannot serve as an axis of celestial co-ordinates. The required great circle RR is obtained by drawing a plane through the centre of the earth parallel to the sensible horizon, or the tangent plane to the earth's surface at the station of the spectator (TT). This is called the Rational Horizon of the observer's station, because it is the plane of reference from which "reckoning" (L. ratio) is made for comparison and computation. It is this great circle of the sphere which is called the Celestial Horizon, or simply The Horizon. As the spectator stands on the surface of the earth the visible pole of the horizon is directly above his head (" zenith ") and the invisible pole directly below his feet ("nadir"), and hence the horizon is said to divide the heavens into the upper and lower hemispheres.

Herschel ("Outlines of Astronomy" Art. 74) in explaining the above terms proceeds on the assumption of a celestial concave with a radius infinite as compared with the earth's radius. The upper figure in the adjoining diagram represents this hypothesis. His definitions are in effect as follows: Sensible Horizon,—The plane touching the earth at the station of the observer, and extended to the celestial concave; Rational Horizon,—The plane through the centre of the earth drawn parallel to the tangent plane at the observer's station; Celestical Horizon,—The great circle in which the planes of the sensible and rational horizon (considered coincident when produced indefinitely) cut the celestial concave. We think, however, that much clearer ideas may be obtained by regarding the eye (E) as the centre of a sphere of definite radius whose use is simply to introduce spherical triangles. The lower figure in the adjoining diagram represents this

hypothesis. [See Oelestial Concave.] The Rational Horizon would in this case be a plane RR drawn through the eye E of the observer, parallel to the sensible horizon see or tangent plane TT. The angle REs is the Dip of the Horizon; and REX and sEX respectively the true and the apparent altitudes of the heavenly body X. If a small sphere be described, concentric with the eye (as by the dotted lines in the figure), are RS is the dip of the horizon, Rx and Sx the true and apparent altitudes of the body X. This way of considering the subject will enable the student to understand better the principle of the Artificial Horizon.

Horizon, Visible.—The boundary of our view, whether of the heavens or of the earth.

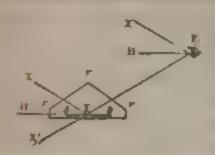

Horizon, Sea. -- The small circle which bounds the view of a spectator in the open sea.

Horizon. Shore.—When the sea-horizon is hidden from view by intervening land, the water-line on the beach often serves the putpose of a horizon in observing altitudes.—See Depression of Horizon.

Horizon, Artificial.—A reflector whose surface is perfectly horizontal, used to observe altitudes on shore. Artificial horizon are of two kinds: (1) those for use on shore, and (2) those for use on board ship

1. (a) The most useful form of the shore artificial horizon is a rectangular trough of quicksilver or other fluid. Quicksilver is the fluid most convenient and the best adapted for obtaining a surface which shall quickly subside after being disturbed. The trough (11) is shallow and a few inches in length; it is fitted with a roof (127) formed of plates of glass with parallel surfaces, to protect the fluid

from the disturbing effects of the wind. The principle is the same in

The image of an object reflected from a horizontal surface (at I) appears so much below the horizontal line on the direction X i as the object itself (X) is above it, the angle of reflection being equal to the angle of incidence.

the angular distance between the object itself and the reflected image (XIX) gives double the altitude (HIX or HEX). It evidently follows that no altitude can be observed in this manner which is greater than half the range of the instrument; thus with a sextant (properly so called) no altitude above 60° can be observed. For altitudes less than 15° the observation is generally impracticable. One advantage of the artificial horizon is, that when the angle shown by the instrument is halved to obtain the angle of elevation, all errors of observation are balved at the same time. The mate mont used for observing is sometimes fixed upon a small pillar. In this actificial horizon an essential condition is the parallelism of the faces of plate glass forming the roof. The effects of refraction may be practically eliminated by making these plates circular discs which adopt of being turned in their own plane. One set of observations having been taken, the plates are turned through 180° and a new set taken, the two being used in combination; or with a common roof the error may be practically eliminated by reversing it. (b) A small mirror of polished metal or of darkened plate-glass is sometimes used as an artificial horizon, its horizontality being ascertained by means of a spirit level placed upon it, and the adjustment effected by means of screws which form its stand. Such an instrument, though convenient and portable, does not give satisfactory results.

2. At sea the celestial bodies are sometimes distinctly visible when the horizon is enveloped in mist; the sea horizon is often disturbed by haze or fog, and by moonlight is often uncertain. Hence the attempts to invent an artificial horizon adapted for use on board ship. Mr. Serson suggested to apply the principle upon which top, when spinning, tends to preserve a vertical position. A pivot carrying a mirror thus rotating would theoretically give the horizontal reflector required; but it failed in practice. Admiral Beechey's contrivance is more successful. The telescope of the sextant is fitted with a balance carrying a glass vane, one half of which is coloured blue to represent the sea-horizon, and to which the celestial object is brought down. The amount of oscillations above and below the level is indicated by divisions on the glass, the value of a division being determined by the maker Other constructions, where the horizon is attached to the sextant, have been tried with more or less muccess.

Horizon-Glass In reflecting astronomical instruments, such the sextant, the horizon glass is that which is fixed in front of the telescope, the lower portion of it being a mirror, the upper transparent. It derives its name from the fact that in taking an altitude the horizon" is seen by direct vision through the portion furthest from the plane of the instrument.

Horizontal.—This qualifying term has two significations which should be carefully distinguished and borne in mind. It would be a great advantage, in the interests of accuracy and simplicity, if this double use of the term were discontinued, especially when there appears to be no necessity for it.

- 1. Horizontal is used in the sense of "parallel with the horizon," whether applied to a line or a plane. It is thus opposed to vertical, which describes a position at right angles or perpendicular to the horizon. Thus "the horizontal diameter of the sun" and "the vertical diameter of the sun" might appear to be phrases admitting use ambiguity. Thus, however, is not the case with the former, though commonly used with this meaning in measuring it for index-error.
- 2. Horizontal is used to describe "the value of an element of a body when "in the horizon." Thus "the horizontal semi-diameter of the moon" is her diameter when she is in the horizon; and so in the phrase "horizontal parallax." These terms are opposed to "the semi-diameter in altitude" and "parallax in altitude."

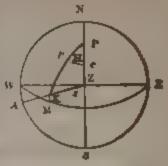

Horizontal Parallax.—The parallax of a celestial body when in the horizon of the observer; distinguished from the Parallax is Altitude.—See Parallax.

Horizontal Projection of the Sphere.—A projection of the sphere—whether orthographic, stereographic, or central—in which the primitive plane or plane of projection coincides with, or is parallel to, the "horizon."—See Projections.

Hour-Angles. -- Generally, angles at the poles of the heavens included between different hour-circles.

Hour-Angle of a Heavenly Body.—The angle at the elevated pole included between the celestial meridian of the observer and the hour-circle passing through the body. Time-angle would be more appropriate term than hour-angle, but the application of the

latter, used in this general sense, is established. It is reckoned positively from the upper culmination of the body westward from 0 to 360°. The hour-angle is sometimes reckoned from the meridian in both directions—positively to the westward, and negatively to the eastward; it would be well however, if it were

always reckoned in conformity with the apparent diurnal motion, just as right ascension is reckoned in conformity with the direct movements of the heavenly bodies. The hour-angle is an important element in most of the problems of celo-navigation, where it is found in a nucleion with the zenith distance of the body z, its polar distance p, and the polar distance of the observer's zenith c (the co-latitude). If a he the altitude of the body, d its declination, and l the latitude of the observer; then  $z = 90^{\circ} - a$ ,  $p = 90^{\circ} \pm d$ ,  $c = 90^{\circ} - l$ ; and from the triangle PZX, we can find H from any of the following formulae:—

1 Cos. \* 
$$\frac{H}{2} = \frac{\sin s, \sin (s-z)}{\sin p, \sin c}$$
Where  $s = \frac{z+p+c}{2}$ 

2. 
$$8 \operatorname{in} \cdot \frac{H}{2} = \frac{\sin \frac{1}{2} (z + p - c) \sin \frac{1}{2} (z - p - c)}{\sin p \cdot \sin c}$$

3. Hav. 
$$H = \sqrt{\frac{\ln v}{\ln v}} \frac{(z+l = d) \ln v}{\cos d \cos t}$$

(xaccording as l and d are of different or the same names. The necessity of this consideration if avoided if we retain p and c in the formula)

...L.hav H=Lsec 
$$d$$
 + Lsec  $l$  - 20  
+  $\frac{1}{2}$  Lhav  $(z+l+d)$  +  $\frac{1}{4}$  Lhav  $(z-l+d)$ .

Hour Angle and Polar Distance.—The polar co-ordinates for defining points of the celestial concave relatively to the position of an observer on the earth's surface. The hour angle is measured at the elevated pole of the heavens from the celestial meridian of the observer, and is reckoned positively from the upper culmination of the point in question westward; the polar distance is measured on the hour-circle which passes through the point from the elevated pole through 150° to the depressed pole. The use of this system is to mark, at any definite moment, the relative position of a heavenly body and the renth of the observer The celestral merchan of the place is the initial position of the radius rector, it is a celestial circle which must be regarded as the projection of the terrestrial meridian, and in rigid connection with it. See Co-ordinates for the

Hour Circles, or Horary Circles.-These were originally circles on globes drawn through the poles 15° from each other, and Now the term is used more Celestial Sphere. comprehensively, and generally for all the great circles passing through the poles of the heavens, marking out the zeniths of all e thus marking intervals of hours. places which have the same time A more appropriate term would time-circles. The hour-circle is regarded as the radius erctor system of polar co-ordinates. This series of circles is co-axial

the " (weles of Declination."

Hurricanes (huracus, a native American word ad through the Spaniarda) - The name by which " Resolving Storm known in the West Indies and Atlantic generally -See Stora Hydra (tik. fispa, "the water-snake") - A constellation

along the south of Cancer, Leo, and Virgo Its principal star, e Hed also Cor Hydre and Alphard, may be found by continuin

from 5 and 7 Ursæ Majoris through Regulus to about half its length; or the line joining Castor and Pollux points it out. Mag. 20: N.A. 1896, R.A. 95 22m, Dec. 8' 12'.

Hydrography (Gk εδωρ, "water"; γράφειν, "to describe," "represent"). The science which treats of the waters of the globe, teaching the art of constructing charts of seas and the adjacent coasts for the special use of the navigator.

Hygrometer (Gk. bypór, "moist"; μέτρον, "measure").-An instrument for measuring the moisture of the atmosphere. The simplest form, and one adapted for ship use, is on Mason's principle, and consists of a combination of two thermometers, which are hung in the shade, in still air, near, but not within three niches of each other One of these thermometers is kept dry, while the bulb of the other is kept damp by having a small strip of wetted linen or cotton ray tred loosely on, while a shred, two or three inches long, hangs down into a small holder of water, and so that the rag is kept wet by capillary action. The moist or wet bulb is cooled by evaporation; the mosater the air the less will be the evaporation, and the drier the air the greater will be the evaporation. Thus the moist-bulb thermometer shows a temperature nearly equal to that of the dry-bulb thermometer when the atmosphere is extremely damp, giving notice of rain, log, or dew; on the other hand, the wet-bulb thermometer shows a temperature considerably less than the other in proportion to the dryness of the atmosphere, presaging dry weather. A Barometer, Thermometer, and Hygrometer together, form a perfect Weather-glass. Any seaman may furnish himself with a rude indicator of the degree of motsture in the atmosphere by hanging up a bit of sea-weed.

I.

Illumination, System of Circles of .- The surface of the earth with reference to its illumination by the sun is divided into two parts-one enlightened, and the other in shadow. The corrections for parallax, refraction, and semi-diameter being made, these portions are hemispheres, and are divided from each other by a great circle. This great circle has been called The Circle of Illumination by most modern writers, old writers calling it The Terminator, from its property of bounding the verges of light and darkness. At all points on the earth's surface situated, at any given moment, on this circle, the sun is in the horizon having the altitude 0°. The line joining the centres of the sun and earth will pierce the surface of the earth at the pole of this great circle, and this point is called The Pole of Illumination, To a spectator situated there the sun is in the zenith, or has an altitude of 90° If parallel to the circle of illumination a system of small circles be drawn, they may appropriately be called Parallels of Illumination, Only one of these, however, palpably marks any difference with respect to the degree of light, viz. The Parallel of Twilight (or Orepusculum), 18° on the side of the Terminator remote from its illuminated pole. But on every point of each parallel the sun has the same altitude, and hence they have been called Parallels of Equal Altitude. This property is the foundation of the method for finding the position of a ship commonly known as Sumner's Method. A similar system of great circle, pole and parallels may be connected with any other heavenly body beaides the sun; i.e. for any star there is a great circle on the earth's surface, at every point of which, at any given moment, it will appear in the horizon, there is one point where it will be in the zenith, and a system of small circles from every point of each of which it will have the same altitude.

such a system the following terms are appropriate: The Great Circle, or simply The Circle of Position, Pole of Position, and Parallels of Position. I have discussed the subject with diagrams and given an historical sketch of its practical application in a paper in Naval Science, January, 1874, "Curves of Position for Determining the Place of a Ship at Sea."—See Position, Parallel of.

Immersion (L. immeryère, "to plunge in") —The commencement of an occultation, or the moment when the occulted body disappears behind the nearer one. The reappearance of the body is called its emersion.

Inperfections of Instruments. In buying an instrument, such as a sextant or compass, it is important to examine its perfection in several essential points. Essential imperfections should lead to its rejection, as no means of adjustment can obviate the resulting errors, nor can these errors be acknowledged and allowed for, or eliminated.

—See under Instruments.

Inclination of the Ecliptic.—The angle which the colliptic makes with the equinoctial, its value being about 23° 27'. More commonly known as the Obliquity, which see.

Inclination of the Needle.—The term generally used by scientific men on shore for the "Dip" of the Magnetic Needle. First noticed by Robert Norman in 1576. The Inclination Needle indicates the angle which the line of magnetic force makes with the horizon, the needle before being magnetized having been suspended at its centre of gravity so as to be free to take up any position —See Dip.

Inclination of Ship —As the deviation of the compass is affected by the heeling over of the ship, it becomes necessary to note, not only the direction of the ship's head, but also her inclination.

Six degrees to starboard or eight degrees to port (for example) may be registered as 6° St., 8° Po. In iron built ships the resulting correction cannot be neglected.—See Compass, Heeling Deviation.

Incommensurable (L. in negative prefix, com, cum "with," mensurables "mensurable").—Not commensurable. Two quantities are said to be incommensurable when they have no common measure; so that when one of them is capable of being expressed in terms of a certain unit the other is not. Thus the side of a square and its diagonal are incommensurable; the diameter and the circumference of a circle are incommensurable. It is necessary that the student should grasp this idea.

Index or Characteristic of a Logarithm.—The integral part of the logarithm, whether positive or negative.—See Logarithms.

Index Correction.—The consequent correction that has to be applied to an observation taken with an instrument that has an

index error. Let O be the zero point of the graduation of the limb, and when the mirrors are placed parallel, let I be the position of the index. Then it is evident that IO (-e) is the index error, and every arc, as OA, observed with the sextant, must be corrected by subtracting e if I be on, and by adding e if I be off, the graduated part of the

hmb. -See under Sextant.

Index Error.—The index error of reflecting astronomical instruments, such as the sextant, is the portion of the graduated limb which lies between the zero point and the index, when the index glass is parallel to the horizon glass.

Index-Glass.—In reflecting astronomical instruments, such as the sextant, the index glass is the mirror at the centre attached to and moving with the "index-bar;" hence its name.

Inferior (L.).—An adjective often used to qualify scientific terms, indicating "below," "lower," "inner"; and opposed to Superior, which indicates "above," "upper," "outer." Thus we have the inferior tide, which occurs at any place when the moon is below the horizon; the inferior culmination of a circumpolar star; the inferior planets, whose orbits are within that of the earth; and the inferior conjunction of an inferior planet.

Inman's Rule.—The method of solving the problem "Latitude by Double Altitude," selected by Dr. Inman, and sometimes distinguished by his name. It is the most general method of solution applying to the same or different heavenly bodies observed either at the same or at different times.—See Latitude, how found.

Inspection.—Solving a problem by inspection is obtaining the result at once by looking into a table, the arguments of which are the data of the problem. Though few problems can be wholly solved in this manner, still the method is used in the different steps and portions of nearly every problem in navigation. The Traverse Table may be thus used to solve any plane right-angled triangle. For example, in the day's work, the diff. long, may be taken out by inspection; and in a Double Altitude "the run" may be found by the use of the same Table. The method of solving problems in Nautical Astronomy by inspection has become very general of late years, more particularly in connection with the Time Azimuth, by means of the Burdwood and Davis Tables, and with the Ex-Meridian, for which Tables have been published by Towson and other authors.

Instruments; Imperfections, Adjustments, Errors. -Under the head of Imperfections of Instruments are included actual imperfections in their construction, such as easontially impair their efficiency. It is important, when buying an instrument, to be acquainted with the points where such imperfections may be expected and with the means of detecting them. Inferior instruments will thus be rejected. Adjustments of Instruments is a term having reference to sources of error arising from those fittings of the component parts of the instrument which are constantly hable to get out of order, and some of which have to be rearranged according to circumstances. machinery is provided to rectify the instrument. An observer must be acquainted with the manner of testing on all points, and the means of making the several adjustments. Errors of Instruments is a phrase indicating such points as are permitted to remain unadjusted in an instrument when used. They are ackowledged and determined by experiment, so that allowance may be made for them. An observer constantly satisfies himself upon the error of his instrument.

Intercalary Day.—The day "intercalated" or inserted in leap years to make up for the odd hours, minutes, etc., neglected by considering the ordinary civil year to consist of 365 integer days.—See Calendar.

Interpolation.—The finding a value of an element which falls between two given values. This process is called into constant requisition in navigation. The different elements tabulated in the "Nautical Almanac" are given for particular times at Greenwich, and their value at any instant between two of these times may be found by working a proportion in the ordinary way, or by proportional logarithms. The method, however, practically adopted, in most cases, is that rendered available by the variation of the elements

being now given in the "Nautical Almanac," those of the sun for 1h, and those of the moon for 10m. In most cases an approximation is aufficient. When extreme precision, however, is required it has to be remembered that, in general, these elements do not change uniformly, and a correction has to be applied which is called the Liquition of Necond Differences. In general when the declination or other element is required with more than ordinary exactness attention should be paid to the precept of the Nautical Almanac (p. 520 of the Almanac for 1896) that the hourly variation given in the Almanac for noon requires to be reduced to midway between noon and the time at which the element is required. This is an exceedingly simple practical method of applying the correction for "Second Differences." See Second Differences.

Iron-built Ships —The application of iron to shipbuilding has necessitated a change in the treatment of ship's compasses,—See Compass Deviation in Iron Ships.

Irradiation (L. irradiare, "to shine upon"). The apparent enlargement of the disc of a heavenly body, caused by the vivid impression of its light on the eye. This phenomenon is perhaps best illustrated by the appearance of "the new moon in the old moon's arms," the slender bright crescent appearing to the eye to be a portion of a larger circle than the part of the disc which is visible in the shade. The effect of irradiation on the apparent diameter of the sun may amount to as much as 6, but so small a quantity as this is of no practical importance. It may, however, be removed by observing both limbs.

Isoclinic Lines (Gk. toes, "equal," «Mivew, " to make slope").
--Lines of equal magnetic dip -- See Magnetism Charts.

Isogonic Lines (Gk. 1001, "equal," yarla, "an angle"). - Lines of equal magnetic variation - See Magnetism Charts.

Isodynamic Lines (ik. loos, "equal," δυναμιτ, "force").— Lines of equal magnetic force.—See Magnetism Charts.

Ivory's Rule —A method of solving the problem "Latitude by Double Altitude" of the same body. It applies strictly only to such bodies as do not change their declination in the interval; but is also practically available in the case of the sun, by using the mean of the two polar distances; and similarly for the moon at the seasons of her greatest declination N. and S., when the change of that element is very slow. The triangles formed by the polar distances, zenith distances, and distance of the bodies, are, by drawing perpendiculars, out up into right angled triangles, the successive solution of which leads to the determination of the co-latitude, and hence to the latitude.—See Latitude, how found.

J.

Jacob's Staff. A name sometimes given to the Cross-staff.

Jupiter named after the king of the Roman gods. The largest planet of the solar system, its diameter being about 11½ times that of the earth, and its bulk about 1500 times greater. It revolves at about 5½ times the distance of the earth from the sun, next in order after the numer are group of small bodies called the asteroids. It is accompanied by four moons or satellites. [See Planets.] The apparent angular diameter of Jupiter varies from 30 to 46". It is a body of the greatest importance to the navigator; for besides serving in a pre eminent manner the ordinary purposes of bright stars, such as by its altitude determining the latitude and, by its lunar distances, furnishing the means of finding the longitude), the colipses of Jupiter's

satellites give an independent method of obtaining the longitude.— See Longitude, how found. Symbol 4.

Journal, Ship's. See Log-book.

Julian Calendar The Calendar as reconstituted by Julius Casar (Pontifex Maximus).—See Calendar.

#### Κ.

Kilométer (Gk. χίλιοι, "a thousand," μέτρον, "a measure," Fr 'metre) — A French measure of length, being 1000 metres, and equal to about § of an English mile. It is sometimes called The Metrical Mile.—See Métre, Mile.

Knot.—A division of the log-line; so called from the line being divided into equal parts by pieces of string rove through the strands and knotted in order. When the 285 log-glass is used, the length of the knot is 47 29 feet.—See Log.

Knot.—A useful abbreviation of the unit used to indicate the apeed of a ship, which may be taken to be synonymous with the expression "mile per hour". In practice it is not unusual to confound it with the word "mile" used not as a rate, but as a distance. Thus we speak of a ship steaming 15 knots, instead of 15 miles per hour. But it would be wrong to say that the two ships were 15 knots apart. In such a case we gain nothing but confusion by the substitution of "Knot" for mile. So also there is no advantage by saying that a ship was steaming 15 knots per hour, since the unit of time as well as of distance is implied in the simple word "Knot."

#### L.

1 -Of the letters used to register the state of the weather in the log-book, 1 indicates " Lightning."

L. The initial of logarithm. It is used to indicate the tabular logarithm in contradistriction to the actual logarithm, which is referred to by the abbreviation log. -See Log

## Lagging -See Tide day, Priming and Lagging.

Land.—On leaving the land a departure should be secured at the latest period possible. To insure this, it should be set at the close and dawn of day, and at the coming on of a fog. On making the land it is prudent to charge the ship's place with some inaccuracy and keep a most vigilant look out; when any uncertainty rests on the longitude, it will be well to make the latitude of the port and then run along the parallel. As soon as the land is made the ship should at once be laid off by the reckoning. Caution is required on special points, such as currents, coral reefs, etc., according to the nature of the region. Among the indications of the neighbourhood of land which may at times prove valuable, may be mentioned the presence of birds, and a lowering in the temperature of the surface water.

Landfall. The land first sighted at the termination of a voyage.

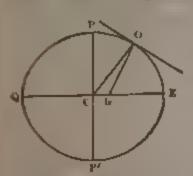

To make a good landfall is to make the land as expected.

Landmark. A conspicuous object on shore, the bearings of which give the position of the ship and serve to guide her course

Latitude (L. latitude, "breadth"). See Longitude and Latitude

Latitude of an Observer. When the earth is regarded as a sphere the latitude of the place of an observer is its angular distance from the equator, and it is measured by the arc of the terrestrial merid an if the observer intercepted between the equator and the place, or by the corresponding angle at the centre of the sphere. The earth, however, is in reality an obtate spheroid, and when its

departure from the spherical form is taken into consideration, this are and angle cease to measure each other. Hence the distinction between the Latitude on the Spheroid and the Latitude on the Sphere, or, in other terms also used, the Geographical or Normal Latitude and the Geocentric or Central Latitude, or the True Latitude and Reduced Latitude. The geographical, normal, or true latitude, is the angle (EGO) which the normal, or perpendicular to the earth's auriace at the place, makes with the plane of the equator.

The geocentric, central, or reduced latitude, is the angle (ECO) which the line joining the place and the centre of the earth makes with the plane of the equator. The former of these is the latitude as determined by astronomical observations, the latter is deduced from it by the

application of the correction tabulated under the heading "Reduction of the Latitude of Place for Figure of the Earth" Latitude is reckoned from the equator north and south to the poles from 0 to 90°. Longitude and latitude are the co-ordinates for defining position on the earth's surface.—See Longitude and Latitude.

Latitude, Reduction of.—The correction necessary to convert True Latitude into Reduced. This correction is given in Tables as "Reduction of the Latitude of Place for Figure of the Earth." Being the angle between the lines which would be vertical on the two suppositions, this quantity is also called the "Angle of the Perticul." It vanishes at the equator and at the poles, and attains its maximum when cot lat. =  $\sqrt{1-e^2}$ , or at about 45" of latitude.

Latitude (Terrestrial), Parallels of.—Small circles of the terrestrial sphere parallel to the equator. They mark all the places on the earth which have the same latitude, and places of the same latitude are said to "be on the same parallel." Compare "Parallels of Declination," "Parallels of Latitude (Celestial)," "Parallels of Altitude." See Co-ordinates for the Surface of a Sphere.

Latitude, Difference of.—The difference of latitude (abbreviated Diff Lat.) between two places is the arc of a meridian intercepted between their parallels of latitude.—See under Difference.

Latitude from. - The latitude of the place sailed from.

Latitude in, or Latitude to.—The latitude of the place sailed to.

Latitude in, and Longitude in.—Problem in geo-navigation. To find the latitude in and the longitude in, having given the latitude from, the longitude from, and the course and distance between the two places. Two general methods of solution --

(I.) By "MERIDIONAL PARTS"; from the formule-

True diff lat, = dist x cos course

: log true diff. lat. = log. dist. + L cos course - 10

Diff. long. = mer. diff lat. × tan course

log diff. long. = log mer. diff. lat. + L tan course - 10.

(II.) By "MIDDLE LATITUDE"; from the formulæ-

True diff. lat. = dist, x cos course

.. log, true diff. lat = log. dist. + L cos course 10.

Dep. -true diff. lat. x tan course Diff. long. =dep. x sec mid. lat ∴ log. diff long. = log. tr. diff. lat. + L tan course + L see mid. lat. - 20.
In the special case of "PARALLEL SAILING"; the lat lin is the same as the lat. from; the long. in is found from the formula.—

Diff. long. = dist.  $\times$  sec lat.  $\therefore$  log diff. long. = log. dist.  $\pm$  L sec lat. - 10.

#### Latitude, how found-

#### I. IN GEO-NAVIGATION.

The latitude at the preceeding noon being given, together with the distance run, and the course made good since, the latitude is found from the formula—

> True diff. lat. =dist. × cos course ∴ log tr. diff. lat. =log dist. + L cos course - 10.

#### II.-IN CELO-NAVIGATION.

In the figures of the following articles, the projection is uniformly made on the plane of the horizon NWSE; Z is the zenith; EQW the equator; P the north pole; P the south pole, and NZS the meridian. The letters X and Y are used to indicate the position of the body or bodies observed. The altitude is indicated by a, the senith distance by z, the declination by d, the polar distance by p, the co-latitude (or polar distance of the observer's zenith) by c, and the latitude by l. It must also be premised that the elevation of the pole is equal to the latitude of the place; for NP=NZ-ZP=90°-ZP-QP ZP=QZ.

The body observed may be the sun, the moon, a star, or a planet, the corrections for finding the true altitude from the observed, and for finding the declination at the moment of observation, varying in each case.

There are three classes of observations for determining the latitude. (I.) Meridian Altitudes; (II.) Circum-meridian Altitudes, or altitudes when the body is near the meridian, and which can be "reduced" to corresponding meridian altitudes; and (III.) Ex-meridian Altitudes, or altitudes when the body is away from the meridian: pairs of such altitudes are "combined" for the resolution of the problem.

## (I.) MERIDIAN ALTITUDES.

(i.) By an observation of One Meridian Altitude of a body.

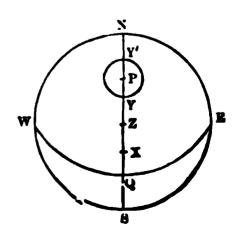

# 1. Above the elevated pole.

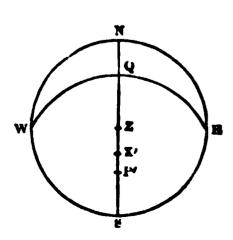

If d be considered  $\pm$  according as it and the elevated pole are of the same different name; and z (measuring always from Z) be considered  $\pm$  according as it reckoned from the elevated pole; then in every case,

$$l=z+d$$

The different cases may, however, be considered separately.

(a) If the body (as X) is on the same side of the elevated pole and Z,

then according as l and d are of the  $\frac{\text{same}}{\text{different}}$  name.

$$l = z \pm d$$

(b) If the body (as X') is between the elevated pole and Z, then

$$l = d$$
 or  $l = a - p$ .  
2. Below the elevated pote (as Y')  
 $l = a + p$  or  $l = a + 90^{\circ} - d$ .

(ii.) By combining observations of Two meridian altitudes of a body whose declination may be considered constant, viz., at the upper and lower culminations, a = NY,  $a_i = NY'$ 

then 
$$l = \frac{1}{2} (a + a_i)$$
.

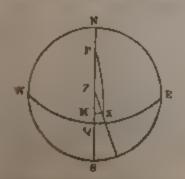

(II.) CIRCUM-MEBIDIAN ALTITUDES.

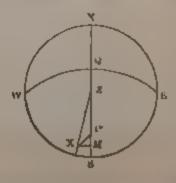

Method i. - Using Estimated Latitude.

Observe a number of altitudes when the body is near the meridian, noting the time, and, when practicable, an equal number should be taken on each side of the meridian. By this means a much more accurate result may be obtained than by taking a single altitude.

1. Above the elevated pole.

Let z' be the mean true zenith distance deduced from the mean of the observed altitudes, and z the unknown meridian zenith distance;

h the mean hour-angle found from the times; let l' be the approximate and l the true latitude. Then from the triangle PZX (the upper or lower sign being used according as l' and d have the same or different names),

$$\cos h = \frac{\cos z' \mp \sin l' \sin d}{\cos l' \cos d}$$

Whence is deduced

Vers 
$$(l' \pm d) = \text{vers } z' - \cos l' \cos d \text{ vers } h$$
  

$$\therefore \text{ Vers } z = \text{vers } z' - \cos l' \cos d \text{ vers } h.$$

Assume vers  $\rho = \cos l' \cos d$  vers h

So that hav.  $\rho = \cos l' \cos d$  hav. h

.. L hav.  $\rho = L \cos l' + L \cos d + L \text{ hav. } h - 20$ vers  $z = \text{vers } z' - \text{vers } \rho$ . Then as in (I.) 1, l = z + d.

If the latitude thus found differs much from the assumed latitude, the calculation must be repeated with the new value l instead l', and thus a nearer approximation to the true latitude will be found.

## 2. Below the elevated pole.

If a', be the mean true altitude, and a', the meridian altitude below the pole, it may be similarly proved,

Vers 
$$(90^{\circ} + a_{i}) = \text{vers } (90^{\circ} + a_{i}) - \cos t \cos d \text{ vers } (12^{\text{h}} \sim h)$$
  
= vers  $(90^{\circ} + a_{i}) - \text{vers } \rho_{i}$ 

Then as in (I.) 2,  $l=90^{\circ}+a_{i}-d$ .

Method ii. A very simple practical method of treating an observation near the meridian has recently been proposed by Mr. J. White, R.N., by the aid of the Table of Meridianal Parts.

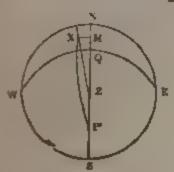

Considering the zenith distance (z) as a meridian zenith distance by adding or subtracting the declination (d) we obtain an approximate latitude (l').

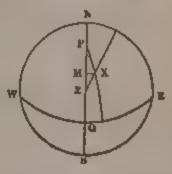

With l, d, and h we look out the azimuth (z) as accurately as may be in Burdwood or Davis. Then if l is the real value of the latitude required

Mor. Parts for l = Mer. Parts for  $l' \pm \theta$ 

where Mer. Parts for  $\theta = \text{Mer. Parts}$  for  $(90^{\circ} - h) + \text{Mer. Parts}$  for  $(Z - 90^{\circ})$ , h being the hour angle of the body.

Method ii.—Independently of Approximate Latitude.

From X drop a perpendicular XM  $(=\phi)$  upon the meridian, and let MP = M, MZ = N; then from the right-angled triangles XMP, XMZ,

Cos h - tan M cot p

.. Tan M = cos h cot d

.. cos N = sin a cosec d cos M

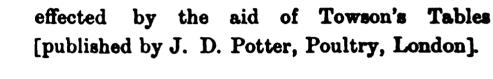

L tan  $M = L \cos h + L \cot d = 10$ ; L cos  $N = L \sin a + L \csc d + L \cos M - 20$ . Co-latitude M = N,

the upper sign being taken if the sun (the body observed) passes the meridian outside the pole and zenith, and the lower if it passes between them. If the latitude and declination are of different names, tan M is negative, and the arc taken from the tables must be

subtracted from 180°. In finding tan M, unless a proportion is used for odd seconds, the result may be several minutes in error.

The "estimated latitude" method is the better of the two described.

The "Reduction to the Meridian," or process of reducing an altitude observed near the meridian to the meridian altitude, may be

Method iii.—Case of the Polar Star.

The preceding formulæ are always available in the case of the Polar Star, since that body by reason of its small polar distance is never

far from the meridian.

In this case however it is better to employ the special formula.

$$l=a-p\cos h+\frac{1}{2}\sin 1''(p\sin h)^2\tan a$$
.

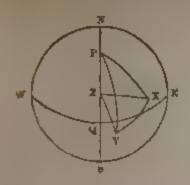

The labour is very much diminished by the use of tables derived from this expression and given in the "Nautical Almanac."

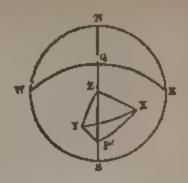

## (III.) DOUBLE ALTITUDE.

The latitude is found by the combination of two such altitudes either of the same body at different times, or different bodies at the same time, or of different bodies at different times.

# Method i.—Direct. General.

Let p and p' be the polar distances of the body or bodies in the positions X and Y (X having the greater azimuth); z and z' the zenith distances; P the polar angle, which, in the case of the same body at different times, is the "elapsed time"; in the case of different bodies

at the same tune, is the difference of the right ascensions; and in the case of two bodies observed at different times, is a combination of the slapsed time and the difference of right ascensions. Then we successively determine the following arcs, thus finally getting the co-intitude, and hence the latitude:—

Arc 1.-XY. In the triangle XPY,

Vers XY - vers (p - p') + vers SHavers S =  $\sin p \sin p'$  Hav. P

or in the logarithmic form,

In taking the observations, the nearer the difference of azimuth of the two bodies or positions approaches 90° the better, and the less will be the effects on the resulting latitude of any errors in the observed altitudes. When the ship has moved between the two observations the first altitude must be corrected for the "run" of the ship in the interval. This may be done with the aid of the Traverse Table, entering with the angle between the bearing of the body at the first observation and the ship's course made good in the interval as ja course, and the distance run as a distance; the corresponding diff lat, will be the correction, to be added when the course is less than eight points, to be subtracted when greater. The resulting latitude will be that of the second place of observation. [Run]

Before leaving the subject of the general Double Altitude it may be well to add that though combined altitudes of this description are now generally worked out by one or other of the Summer methods it ought not to be overlooked that such methods furnish results that are only approximate, and should therefore be practised with some caution and discrimination, while the old Double Altitude process, based as it is upon the principles of Spherical Trigonometry is mathematically rigorous and true.

Method ii.—Ivory's. For cases where the declination is considered the same for the two positions.

Draw PB the perpendicular bisecting XY in B; and ZA the

perpendicular from the zenith upon PB (or PB produced) meeting it in A. Then we successively determine the following arcs:—

Arc 1. -BX.

$$Sin BX = \sin \frac{P}{2} \sin p$$

∴ L sin i. = ½ L hav H + L cos d - 5.

Arc ii. -PB,

$$\mathbf{Cos} \ \mathbf{PB} = \ \frac{\mathbf{cos} \ p}{\mathbf{cos} \ \mathbf{BX}}$$

∴ L coa it. = L sin d + L sec i, +10.

(When the polar distance exceeds 90° the supplement of the arc found in the tables must be taken.)

Arc iii. -ZA.

$$\sin ZA = \frac{\cos \frac{1}{2} (a+a') \sin \frac{1}{2} (a-a')}{\sin BX}$$

 $\therefore \text{ L sin iii.} = \text{L cosec i.} + \text{L cos} \frac{1}{2} (a+a') + \text{L sin } \frac{1}{2} (a-a') - 20.$  Arc iv. - BA.

$$\cos BA = \frac{\sin \frac{1}{2} (a+a') \cos \frac{1}{2} (a-a')}{\cos BX \cos ZA}$$

 $\therefore L \cos iv. = L \sec i. + L \sec iii. + L \sin \frac{1}{4} (a+a')$  $+ L \cos \frac{1}{4} (a-a') - 30.$ 

Arc v. - PA.

$$PA = PB \mp BA$$

$$v = ii = iv$$
.

Arc vi. —PZ (co-latitude).

 $\therefore$  L sin lat = L cos v. + L cos iii. - 10.

This method may be rendered general by applying a correction  $\theta$  to the computed latitude for any change of declination in the interval between the two observations. By this means it may be used for double altitudes of the sun. Let c be the change of declination in half the elapsed time, then—

$$\theta = c \frac{\sin iii.}{\cos l \sin \frac{P}{2}}$$

This correction is additive when the second altitude is the greater and the polar distance decreasing, or when the second altitude is the less and the polar distance increasing; otherwise it is subtractive.

Another way of obtaining accuracy is to use the mean of the polar distances.

Latitude of a Heavenly Body. The angular distance of the body from the ecliptic. It is measured by the arc of the circle of latitude passing through the place of the body, intercepted between the ecliptic and that place, or by the corresponding angle at the centre of the sphere. Latitudes are reckoned from the ecliptic to its poles, north and south from 0 to 90°. Longitude and latitude are the ecliptic co-ordinates for defining the positions of points on the celestral concave, and indicating their positions relatively to each other — See Longitude and Latitude.

Latitude (Celestial), Circles of.—Great circles of the celestial concave passing through the poles of the ecliptic, and so called because "latitude" is measured on them. They are also called "Circles of Longitude," as marking out all points that have the same longitude.—See Oo-ordinates for the Celestial Sphere.

Latitude (Celestial), Parallels of -Lesser circles of the celestial concave parallel to the cel pile. They mark all the points of the heavens which have the same latitude. Compare "Parallels of Declination," "Parallels of Aititude."—See Co-ordinates for the Celestial Sphere.

Latitude, Heliocentric and Geocentric (Ck. 1)\lambda \text{tos, "the sun"; \( \gamma\_0 \), "the earth"; and \( \sigma \sigma \gamma \text{pos, "the centre"} \),—Terms applied especially to the planets. The distance of the planets from the earth is small compared with that of the fixed stars, and hence the place of any one of them in the celestial concave varies with the position of the spectator in different parts of the earth's orbit. Thus, viewed from the earth as centre, we have the secontric place of a planet

and the corresponding geocentric latitude and longitude. On the contrary, if viewed from the sun as centre we have the heliocentric place of the planet, and the corresponding heliocentric latitude and longitude. The geocentric differs from the heliocentric place of a planet by reason of that parallactic change of apparent situation which arises from the earth's motion in her orbit.

Lead. A piece of lead attached to a string used for taking soundings, or for certifying that the water is above a certain depth.

Lead-arming — A lump of tailow pressed into the lower end of the sounding-lead, for the purpose of ascertaining the nature of the sea bottom.

Lead-line.—The line attached to the lead used for taking soundings. This line is marked at the 10 fathoms (leather with a round hole) and the 20 fathoms (piece of cord with two knots); intermediate fathoms between these, at 3 (leather), 5 (white rag), 7 (red rag); also at 13 (blue rag), 15 (white rag), 17 (red rag). These depths are called Marks, and those which are not thus indicated Deeps; and the leadsman, in calling the soundings, cries either, "By the Mark," or "By the Deep." The word "deep" is a corruption of dip, for in estimating the depth with the hand lead, when it lies between the fathoms marked the line has to be lifted out of the water and "dipped" down again. The only fractions of a fathom used are a half and a quarter-e g 74 fathoms is "and a half seven '; 71 is "a quarter less eight." The hand lead-line is limited to 20 fathoms. The deep sea lead line is marked in a similar manner up to 20 fathoms, after which every subsequent 10 fathoms is indicated by a piece of cord with an additional knot, and between these a piece of leather marks the 5 fathoms

Lead, hand. The sounding-lead for shallow water, so called from it being thrown by the "hand." The use of it is not only to obtain soundings, but to satisfy the pilot that the water is above a certain depth. The "leadsman," standing in the chains, swings the lead once or twice round and then "casta" it forward as far as he can. He draws the line tight from the lead at the instant the ship in her progress places him perpendicularly over it. It descends about 10 fathoms in the first aix seconds. The hand-lead weighs 14 lbs., and is attached to about 25 fathoms of line. A small lead of about 5lbs. or 6lbs. is sometimes used.

Lead, Deep-sea.—The sounding-lead for deep water. Its weight is 28 lbs., and it is attached to a line of 100 fathoms or more wound on a reel. In heaving it, the ship's way is reduced if necessary, and the line having been passed aft outside of all, the lead is carried forward and dropped from the lee cathead, or fore-chains. The error of the soundings is generally in excess, as the line can seldom be stretched straight from the lead.

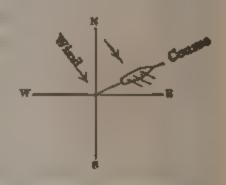

Str William Thomson has invented a "Navigational Sounding Machine" for the purpose of obtaining soundings from a ship running at full speed in water of any depth not exceeding 100 or 150 fathoms. See "Journal of the Royal United Service Institution," vol. xxii. No. xciv.

League (Sp. legua) .- Three pautical miles.

Leap Year or Bissextile. -The Year which the calendar regulates to consist of 365 instead of 365 days. It derives its name from leaping over a day more than the ordinary year, which day was not legally recognised. The 24th of February and the following day in the bissextile year were considered in the Roman law as one day;

and so in the Luglish calendar, by statute 21 Henry III., the intercalated day and that preceding it were considered legally as one ("Computetur desille et dies proxime precedens pro uno die").— See Bissextile and Calendar.

Leeway The angle which the ship's track indicated by her wake makes with her fore and aft line or keel. When the ship is not going before the wind she will not only be forced forward in the direction of her head, but, in consequence of the wind pressing against her sideways, her actual course will be to

"leeward" of the apparent course that she is lying Experience and observation are required to judge what amount of leeway to allow in each case. It is one of the corrections to be applied in reducing the compass course to the true course in the day's work; the correction being allowed to the right when the ship is on the port tack, i.e. port side to we dward, and to the left when on the starboard tack. A simple figure will always remove any doubt in making such corrections.

Length of a Wave. - The horizontal distance between two adjacent crests, or two adjacent hollows.

Leo, Constellation of (L. "The Lion").—The fifth constellation of the zo trac, coming between Cancer and Virgo, and situated near the Great Bear on the opposite side of it to the pole star. Its four principal stars form a trapezium. a Leonis called also Cor Leonis ("The Lions Heart") and Regulus, may be found by joining a and # Ursa Majoris ("The Pointers") and continuing the

line about twice the length of that constellation; this line also passes γ Leonis. β Leonis, called also Denebola ("The Lion's Tail"), is found by joining η Ursæ Majoris (the last star in the tail of the Great Bear) with Cor Caroli, and continuing it about twice its length. a Leonis, Mag. 1.4: N.A. 1896, R.A. 10h 3m, Dec. + 12° 29°, β Leonis, Mag 2.2. N.A. 1896, R.A. 11h 44m, Dec. + 15° 9′, γ Leonis, Mag 2.2: N.A. 1896, R.A. 10h 14m, Dec. + 20° 22′, δ Leonis, Mag 2.8: N.A. 1896, R.A. 11h 9m, Dec. + 21° 16′.

Leo, Sign of.—The fifth sign of the ecliptic, including from 120° to 150° of longitude. Owing to the precession of the equinoxes, the constellation Cancer, and not Leo, is at present in this sign. The sun is in Leo from 22nd July to 23rd August. Symbol  $\Omega$ .

Lesser or Small Circles —Lesser or Small Circles of the Sphere are sections by planes which do not pass through the centre. Thus parallels of latitude are lesser circles of the terrestrial sphere; parallels of declination, parallels of latitude, and parallels of altitude are lesser circles of the celestial sphere.—See Circles of the Sphere.

Level of the Sea.—The zero plane from which heights and depths are reckoned. As the actual sea-level is constantly varying with the tides, it is necessary to define more particularly the standard for comparison. The Mean Level of the Sea is the middle plane between the levels of high and low water. Though the range of the tide may vary considerably, this mean level fluctuates within very narrow limits.

Level, Spirit.—An instrument for ascertaining the horizontality of a line or plane. It consists of a hollow glass tube of uniform bore closed at both ends, and nearly filled with a fluid of great mobility, such as spirit wine or sulphuric ether, an air-bubble remaining enclosed. The tube is not quite straight, but has a slight uniform curvature, the convex side being placed upwards. The air-bubble will always occupy the highest position, and this will be the middle point of the tube when the instrument stands in a perfectly horizontal position as regards it length. To ascertain the horizontality of a given line, the level is first placed upon it, and the position of the bubble noted; it is then reversed end for end, and the bubble must remain in the same position as before. For a plane the test must be repeated in a direction perpendicular to the first pair of observations. Astronomical levels are furnished with a divided scale by which the position of the ends of the bubble can be accurately noted.

Libra, Constellation of (L. "The Balance").—The seventh constellation of the zodiac, coming between Virgo and Scorpio. It contains two principal stars, a Libra, the North Balance, and \$\beta\$ Libra, the South Balance, the former bisecting the line joining Spica and Antures, the latter with Spica and Arcturus forming a triangle. a Libra, Mag. 3.0; N A. 1896, R. A. 14h 45m, Dec. - 15° 37′. \$\beta\$ Libra, Mag. 2.7; N.A. 1896, R.A. 15h 11m, Dec. - 9° 0′.

Libra, Sign of.—The seventh sign of the ecliptic, including from 180° to 210° of longitude. Owing to the precession of the equinoxes, the constellation Virgo, and not Libra, is at present in the sign. The sun is in Libra from 22nd September to 23rd October. Symbol ...

Libra, First Point of.—The "Autumnal Equinoctial Point," one of the points where the collection crosses the equinoctial, is so-called as being the commencement of the sign Libra.—See Equinoctial Points.

Limb (L. limbus, "a border") -1. The outer edge of the disc of a heavenly body. The initials U. L., L. L., F. L., N. L., stand respectively for "upper limb," "lower limb," "further limb," "nearer limb." In the case of the moon the terminator must not be used as a limb.

2. In astronomical instruments, such as the sextant, the limb is the graduated arc.

Line -"The Line" is the colloquial abbreviation for "The Equinoctial Line." It is where the plane of the equinoctial cuts the surface of the earth, and is therefore coincident with the equator; all places situated upon it have the day of equal length with the night throughout the year, the lengthening of the day owing to refraction and dip being neglected. Passing from one hemisphere to the other is commonly described as "Crossing the Line."

#### Liquid Compass. See Compass.

Local Attraction -The term indicating the magnetic influence on the compass needle of volcanic and other natural magnetic bodies, or of mitificial iron accidentally in the locality of the ship, but extraneous to it. The islands of St. Helena and Ascension are instances of the former, while in the latter are included the iron cranes, water-pipes, and pillars which generally surround our docks, and adjacent iron ships. The term is sometimes applied to the attraction arising from the ship itself, which is the habitat of the compass, but it would be desirable to discontinue this use of the word.

Local Deviation — The angle through which the compass needle is deflected in consequence of the disturbing influence of "local attraction." We suggest the application of the unappropriated simple term "Deflection" for this correction. The simple term

"Deviation" is sufficient, without any qualifying word, to indicate the correction rendered necessary by the effects of the iron of the ship which carries the compass.—See Compass Corrections.

Local Time. Local time is that which is reckoned at each particular place from an epoch or initial instant determined by local convenience; and is thus distinguished from time in the abstract, which is common to the whole universe, and therefore reckoned from an epoch independent of local situation. See under Time.

L. M T -The initials for "Local Mean Time," sometimes used in contradistinction to G. M. T., "Greenwich Mean Time." We, however, recommend adherence to the more common S. M. T., as the correlative of G. M. T. To the navigator S. M. T., "Ship's Mean Time," sounds more practical than Local Mean Time; and if we want it to be received in a more general sense, it may stard for "Mean Time at the Station of Spectator." The objection to the term "Local Mean Time" here is, that Local Time properly includes Greenwich time, for it is opposed to time in the abstract which is common to the whole universe, and therefore reckoned from an epoch independent of local situation.—See Time.

Log (Sax. log, "a bewn trunk of a tree," so called from the word ligen. Du. hygen, because it "lies," as it were immovable. Hence the appropriateness of the name log as applied to the piece of wood which lies dead upon the water and does not participate in the motion of the ship.—A contrivance for ascertaining the rate of a ship through the water. Though the term is derived from the most primitive form, it is now generally applied to all instruments, whether for ascertaining the rate or the actual distance sailed over. These instruments, according to the principle involved, may be divided into three classes I. Dead Logs, II. Screw Logs, III. Liquid Logs. Of the

dist description are the Common Log, the Dutchman's Log, the Ground Log; the second includes what are commonly understood by the Patent Logs such as Massey's and Watker's; while Nupier's Log belongs to the last class.

I. Dead Logs.—The dead log gives its name to "dead reckoning," the method used in geo navigation when the navigator leaves the vicinity of land. The general principle of it is simply this. A body thrown from a ship in motion, as soon as it touches the water ceases to participate in the motion of the vessel, and will be left behind on the surface of the sea.

After a certain short interval, if the distance the ship has passed shead of the stationary float be measured, this will give the rate of mailing with more or less accuracy. In the common log the float is thrown from the stern of the ship and is attached to it, in the Dutchman's log, it is thrown over near the bow and the ship passes by and leaves it behind

1. The Common Log —A dead log consisting of three parts—
the Log-Ship, the Log-Line, and the Log-Gluss. The log ship is the
test which is thrown from the ship and is supposed to remain
tationary while the ship sails on for a definite interval; the log line
measures the distance the ship sails during the interval; and the
log-glass marks this interval. The following is a description of these
several parts, and of the manner of using the instrument.

The Log-Ship ("log-chip"), is a thin wooden quadrant of bout five inches radius, loaded on the circular edge with lead tufficient to make it float upright in the water. The object of this to impede its being dragged through the water by the log-line which is fastened to it; while running out. The manner in which

the log-line is attached is such that this purpose is served only while a measurement is being made. At each end of the arc of the log ship is a hole, through one of which holes the log-line is rove and knotted; a piece of line about eight inches in length is spliced into it at that distance from the log-ship, having at the other end a peg of wood or bone, which, when the log is hove, is firmly pressed into the unoccupied hole. It remains thus while the line is running out, but comes away when the line is being hauled in. The log-ship is sometimes bored with a hole at each of its three corners. Instead of this piece of wood, a canvas bag, with a small hoop at its mouth, like a funnel is sometimes used. A description will also be found in Robertson's Navigation of one in the form of a wooden cone with sinker attached constructed by M. Banquer and published in Paris in 1753, and subsequently with modifications by the Abbe de la Caulle.

2. The Log line is a line of about 150 fathoms, one end being attached as above described to the log ship, and the other fastened to a reel on which the line itself is wound. At ten or twelve fathoms from the log-ship a conspicuous ray of bunting is placed, which marks off what is called the "stray line," a quantity sufficient to let the log-ship go clear of the vessel before time is counted. The rest of the line, which constitutes the log-line proper, is divided into equal portions by bits of string fixed through the strands, and distinguished by the number of knots made in each; hence these divisions are called "knots." The length of a knot on the line depends upon the number of seconds which the log glass used measures. The length of each knot must bear the same ratio to the nautical mile that the time of the glass does to an hour.

Number of feet in 1 knot Number of seconds of glass

Number of seconds in 1 hour

If we use a half-minute glass :-

Feet in a knot = 
$$\frac{30}{3600}$$
 × (feet in a mile).

Formerly it was considered that a degree of a terrestrial great circle was 60 miles, each of 5000 English feet, and the length of a knot was calculated at  $\frac{5000}{120}$  41%, or, in round numbers, 42 feet. This was the old length of the knot; and even after it was found by experience to be too short, rather than alter it mariners often preferred reducing their glasses to 25 or 24 seconds. In 1635, Norwood estimated a degree to measure 367,200 feet (about 69) English miles), and hence, according to him, the nautical mile was  $\frac{367,200}{60}$  or 6120 feet. This gives the length of a knot  $\frac{6120}{120} = 51$  feet.

It is usual now to regard the nautical mile as being 6080 feet. [See Mile.] In this case, with a 30° glass, the length of the knot on log line will be 503 feet; with a 28° glass its length will be 47°3 feet. The knot is supposed to be divided into eight equal parts or "fathoms," that being nearly their actual measurement. It is now customary, however, to use the more convenient decimal subdivision.

The Log-glass is a sand-glass of the same aliape and construction as the old "hour glass." There are two log-glasses used; the Long-glass which runs out in 30s or 28s, and the Short-glass, which runs out in half the time of the long one. If the ship is going less than five nules an hour the long-glass is used; when she is going at a greater rate the short glass is used, and the number of knots indicated doubled, the log-line being constructed for the log-glass. The glasses supplied to the Royal Navy run 28s and 14s.

Heaving the Log. - Using the compound instrument above described is called "Heaving the Log." It is thrown from the stern.

One man holds the reel on which the log-line is wound, and another the log-glass in an almost horizontal position. An officer of the watch, having cautioned the helmsman to keep the ship steady on her course, takes the log ship and presses the peg into its place (except) the vessel is going very fast, when the arrangement is superfluous) he then unwinds a sufficient quantity of line and holds it "faked ! (not "coiled") in his hand, and having ascertained that there is a "clear glass," throws the log ship well out to leeward, so as to clear the eddies of the wake, and in such a manner that it may enter the water perpendicularly, and not fall that upon it. The line run through his hand, and when he feels the bunting rag which marks of the stray line, he cries out "turn!" The glass holder answers "done!" When the vessel is before a heavy sea, the line should be paid out rapidly when the stern is rising, and the reel retarded when the line slackens in consequence of the stern falling. The moment the glass is run out the glass holder cries "stop!" when the reel 🐞 immediately stopped, and the length of the line run out read off, any portion above a definite knot being estimated. This gives the rate of sailing, subject, however, to the effects which may be produced by currents The log is hove every hour, and it should be done also whenever the course is changed.

Log, Adjustments.—The log in all its parts requires to be periodically adjusted. (1) The log ship must be examined and the peg found to fit sufficiently tight. (2). The log-line shrinks unequally and repeatedly requires to be verified. In every ship there should be nails placed in the deck at the proper distance to measure the distance of the knots. When the log line is thus examined it should be wetted. (3) The log glass should often be compared with a watch which has a seconds' hand or with a seconds' pendulum. Such

a pendulum may easily be constructed by hanging from a peg a musket ball by a small thread 38; inches long from the centre of the ball to the peg. In damp weather the sand is retarded and sometimes hangs together. One end of the glass is stopped with a cork, which can be taken out whenever the sand wants drying, or its quantity correcting. It is a very useful accomplishment for an observer on board ship to be able to count accords correctly for a short period.

Log Errors.—The log may be found to be out of adjustment after observations have been made, and then it is necessary to acknowledge the errors and make allowances for them.

Let L be the true length the knot on the line should be, and N the number of such length run out; I the actual false length of the knot on the line, and n the number of these run out. Then, since the same length of line has run out, however it is divided,

$$L \times N = length run out = l \times n$$

$$\therefore \frac{L}{l} = \frac{n}{N}$$

The relations between the true length of the knot L feet, the true time T seconds, the true rate R, and the erroneous values of these respectively I feet, I seconds, and r are given by the formula

$$R = \frac{r}{t} \frac{T}{L}$$
. And as  $\frac{T}{L} = \frac{3600}{6080} = \frac{45}{70} = \frac{3}{5}$  nearly.  $R = \frac{3}{5} \frac{r}{t} \frac{t}{t}$  nearly.

Again, as the whole distance run is proportional to the rate, if D be the correct distance and d the registered erroneous distance, we may unbatitute D for R and d for r in the above.

Hence 
$$0 - \frac{3600}{6080}$$
,  $\frac{dl}{t} = \frac{45}{76}$ ,  $\frac{dl}{t} = \frac{6}{10}$ ,  $\frac{dl}{t}$  nearly.

2. The Dutchman's Log. Propably the oldest form of the dead log, being simply a small piece of wood or other floating body such as an empty bottle without any attachment. Thrown overboard it remains stationary and its position is not subject to any disturbing cause such as the drag of the log line in the common log. To use this for estimating the rate. Two points on the ship's rail, as far apart at possible are marked off and the distance between them accurately Corresponding lines are drawn across the deck measured. perpendicular to the fore-and-aft line. The log is thrown overboard forward in the direction in which the ship is going and when the first mark passes it the exact time is noted and called out and similar when the second mark passes. Let I be the length in feet between the marks, t the interval in seconds between the two marks passing the logandr therate. Then  $r = \frac{1}{2}$ . To find the rate in miles per how 3600-7

we have Rate - 5080 t - 10 t nearly,

3. Log, Ground.—A log adapted for use in shoal water when the set of the tides or current is much affected by the irregularity of the channel or other causes, and when at the same time the shore, i visible, presents no distinct objects by which to fix the ship's position Its characteristic feature is that an anchor takes the place of the float It consists of a small lead, and a line divided as the common log line and a glass corresponding. When have the lead remains fixed at the bottom, and the line thus exhibits the effect of the combined motion of the ship through the water, and of the current.

Current Log. -As it is the relative alteration in the position of the ship and float which the log ship, line and glass determine, \$\( \begin{aligned} \text{the ship} & \text{and glass determine, \$\begin{aligned} \text{the ship} & \text{ the ship is stationary and a current carries away the fluxt, the set and rate of the current may be obtained with this instrument when the ship is at anchor. The same method may be applied at sea by

lowering a boat which can be rendered stationary for the time by means of a heavy weight let down from its stern to the depth of 80 or 100 fathoms. The log is hove from the boat, which gives the "rate" of the current; the "set" is obtained by noting, with the aid of a compass, the direction in which the float drifts.

II. Screw-Logs = These logs give the rate by registering the sectual distance passed over in any time noted. The principle upon which they are constructed is the same as that of the screw propeller of a steamer.

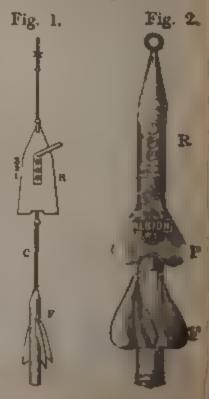

The faster the screw-propeller is made to rotate by the engines, the faster the ship is forced through the water. Hence, conversely, if a free screw be attached to a ship in motion and be dragged through the water by it, the faster the ship goes the more rapid will be the rotation of this screw. In the former case, the screw's rotation in the water propels the ship onwards; and in the second, the onward motion of the ship causes the screw to rotate in the water. And in both cases the number of revolutions actually made will correspond to the whole distance travelled by the ship

These loge are ordinarily spoken of as the Patent Logs there are two in common use called after their Patentees -Massey's and Walker's.

1. Massey's Patent Log.—Mr. Edward Massey was the original patentee of the screw log and has since introduced important improvements in its construction. It consists of two essential parts—the Rotator or Fly F, and the Recorder or Register R. The manner in which these are connected constitutes the chief difference in the different forms of the instrument. The whole instrument is towed astern by a line varying from 20 to 50 fathoms according to the size of the vessel, an essential point being to keep the machine out of the eddy of the ship's wake. As it is thus drawn along through the water in a horizontal position, the oblique direction

of the vance causes the fly to rotate, and this motion is communicated to the wheel-work within the register, and sets in motion the indicate of the dials 1, 2, 3. The vance of the rotator are so adjusted by very accurate experimental trials to the internal machinery of the register, that when the ship has towed the instrument through one mile (whether quickly or with mere steerage way), the index of the first dial will have made one complete revolution, the index of the second will have moved through one tenth, and the index of the third through one hundredth of a revolution, and this is repeated for every subsequent mile. By this means 100 miles can be registered without taking in the log. Every time, however, that the course is changed the log must be taken in, and a fresh commencement of the register made.

In the earlier form, (Fig. 1.) the Rotator F was connected with the Register R by a short cord C; the registering box was flat on one side, thus offering the best resistance to any rotatory motion arising from friction of the swivels of the line which attached it to the Rotator. In the latest forms the "Com al end" and "Albion" No. 1. (Fig. 2) the two parts are united by a central shaft on which the Rotator works while the Register remains in a fixed position. This shaft or "arbor" is a atout drawn tube and is rendered unboudable and unbreakable by its length and the support it receives from discs

planted in the rotator tube itself. The sustaining and equilibrating arrangements obviate any tendency in the parts to become jammed, and consequent liability of the instrument not wholly revolving and failing to register correctly. A float-plate P is attached which prevents the Register revolving, and at the same time compels the whole compact machine to travel horizontally, the object aimed at being to reduce the friction of the Rotator on the axis to a minimum. The vanes of the Rotator are curved or cycloidal to increase the freedom of the rotation.

Another form of the instrument is when the two parts are detached and the Rotator only hove overboard, the Register being fixed inboard. Hence they are called Inhourd, Taffrail, or Boom Logs according to the position in which the Register is placed. They thus afford the advantage of facility of inspection at any moment without hauling in. In Massey's "Inboard Log" and "Deck Trafficial Log," the Register has only one dial instead of three, that there is little setting required. The first named instrument serves the dual functions of a distance-log and a speed guage. On the dial are two circles and two index hands. The inner circle is divided from 1 to 100 nautical miles, and gives the distance run. The outer circle is divided into 60 parts of a mile, and shows the speed per hour by observing the number of these 60th parts passed over by the index-hand in one minute. The connection is effected by a hard planted line through the intervention of "Ixion" a "double lever bar loop log regulator and towing hook " which secures a very perfect delivery of the Rotator's revolutions,

Walker's Patent Ship-Logs.—The logs patented by T. Walker and Son are in principal and general appearance much the same as Massey's. They differ chiefly in the form, extent and

fitting of the arbor or shaft which communicates the motion of the flanges to the indices. Those in one piece—the whole being towed astern—are known as the "Harpoon Ship-Loy;" those in which the Rotator is detached in order that the indicator of the Register may be read on deck are distinguished as the "Cherub" and "Rocket" Ship Logs.

3. Liquid Log.—Of such is Napier's Pressure Log, patented by Mr J. R. Napier. The rate of the ship is indicated by the height of a column of water pressed up in a tube projecting about six inches through the keel and high enough inside to be read with ease. The tube is closed at the bottom, but near the bottom a hole placed in the direction of the ship's bow admits the water, the level of which is the same in the tube and outside the vessel when stationary. But when the ship is under way, the pressure exerted through the hole causes the water to rise in the tube and the height of the water becomes greater as the speed increases. The height of the column in the tube varies with the speed of the ship, and can be measured either directly on a scale by a float, or on a dial by an index connected with the float by a string passing over a pulley

Log-book. The official record of proceedings on board ship, deriving its name from its containing the important register of the log indications. It is strictly a journal, each page being ruled for one day. In the merchant service it is still the custom to begin the day at non. In the Royal Navy the time is reckoned as on shore, from indiright, and the hours carried on to 12 or boon, and then to 12 or undought again. A form is authorized for use in Her Majesty's Navy.

log —The abbreviation of legarithm, as log. N, log sin a Table of the logarithms of the trigonometrical ratios give the actual logarithms increased by 10 in order that the inconvenience of negative

characteristics may be avoided in the work of computation. Thus, tab,  $\log \sin a = \log$ , an a + 10, tab,  $\log$ , hav  $a = \log$ , hav a + 10. To avoid all confusion the large mitial letter L may with advantage be used for tab,  $\log$ , the abbreviation  $\log$ , being restricted to signify the actual logarithm. Thus,  $\log$ ,  $\sin a = L \sin a = 10$ ,  $\log$ , hav a = L hav a = 10.

Logarithms (Gk  $\lambda \alpha \gamma \hat{\omega} \nu d\rho \partial \mu d\rho$ , "the number of ratios," i.e. the number of times an increase is made in a certain ratio when approximating to a given quantity). — Definition.—The logarithm of a number N is the value of x, which satisfies the equation a - N, where a is some given number, and is called the Base. The logarithm of N to base a is written log. a N — Example — If a be 10, the logarithm of 100 is 2, and that of 1000 is 3, and that of any number between 100 to 1000 will be greater than 2 and less than 3, so that it may be represented by 2 and a fraction, the fraction being indicated by a decimal. The integral part of a logarithm is called the Characteristic or Index, and the decimal part the Mantissa (L. over-weight). Whatever positive value different from unity we give to a, it is possible to find the value of x, corresponding to all values of N, i.e. to find the logarithms of all numbers to the base a. These can then be registered in tables for use.

Logarithms, Computation by.—The use of logarithms greatly facilitates long calculations, for by the aid of a table of logarithms (1) multiplication may be performed by addition. (2) dension by subtraction, (3) involution by multiplication, and (4) evolution by division. For let N and N' be any two numbers, x and z' their logarithms to base q. Then ax = N, ax' = N'

 $N.N' = ax \times ax' = ax + x'$  by def.  $x + x' = \log_{10} N.N'$ 

$$\log_{a} N.N' = \log_{a} N + \log_{a} N'$$

$$\frac{N}{N'} = \frac{ax}{ax'} = ax - x'$$

$$x - x' = \log_{a} \frac{N}{N}$$

$$\log_{a} \frac{N}{N} = \log_{a} N - \log_{a} N'$$

$$N' = (ax) / p = a / x$$

$$px = \log_{a} N / p$$

$$\log_{a} N / p = p \log_{a} N$$

$$\log_{a} N / p = p \log_{a} N$$

$$\frac{x}{N} = (ax) / r = a'$$

$$\frac{x}{r} = \log_{a} x / N$$

$$\log_{a} x / N = \log_{a} x$$

$$(3)$$

The logarithms of the numbers N and N' are found in the tables, and the operation of addition, subtraction, multiplication, or division, as the case may be, performed on these; the result is regarded as a logarithm, and then the tables conversely used enable us to find the number corresponding to it. This quantity is the object of our investigation.

Logarithms, Systems of.—In the equation  $a^{\mu} = N$ , a may be any positive quantity different from unity. There are, however, two systems of logarithms which posses peculiar advantages, called after their inventors, Napierian logarithms and Briggs' logarithms.

1. In the Napierian system the base is  $\epsilon$ , which represents the incommensurable quantity  $1+1+\frac{1}{1\cdot 2}+\frac{1}{1\cdot 2\cdot 3}+\frac{1}{1\cdot 2\cdot 3}+\frac{1}{1\cdot 2\cdot 3\cdot 4}+\dots$  or 2.7182818.... This is a convenient base for analytical purposes, and is applied in the actual calculation of logarithms. Thus,

$$N = a \cdot s = a \log_{a} \times \log_{e} $

Hence to find the logarithms to base a, the Napierian logarithms are multiplied by the quantity  $\frac{1}{\log s}$ . This quantity, which is easily calculated, is called the modulus (L. "measure of proportion")

2 In Briggs' logarithms the base is 10, the same as the base of the common asystem of notation. The great advantage of this system is that the same decimal part serves for the logarithms of all numbers which differ from one another only in the position of the place of units relatively to the significant digits. Let Log 1, N + + m, where c is the characteristic or integral part, and m the mantisse or decimal part. Then N × 10# will be a whole number, having the same significant digits as N, but with its units' place removed p places to the right. Then

log 10 (N × 10¢) = log. 10 N + log 10 10¢ = (c + p) + m which has c + p for its characteristic, and the same in integral as log. 10 N. Again  $\frac{N}{10p}$  will be a decimal, having the same significant digits as N, but with its place of units removed p places in the left. Then  $\frac{N}{10p} = \log_{10} \left(N \times 10^{-p}\right) = \log_{10} N + \log_{10} 10^{-p}$  in  $\frac{(c - p + m) \text{ or }}{(c - p + m)}$  according as  $\frac{N}{10p} > \text{or } < \text{than } 1$ . In this case then also, provided

the logarithm be expressed so that the characteristic only is negative, the mantissa is the same as that of  $\log_{10} N$ . Hence in tables of these logarithms the mantissa only are registered, and are always positive. The characteristic is assigned by the following rule:—The characteristic is equal to the number of places from the units' place, which is not included, to that of the most important digit, positive or negative according as the number itself is greater or less than unity. Where the two parts of the logarithm are of different signs, the negative sign is placed above the characteristic thus, 3 269746. Good logarithmic tables are usually calculated for 4 or 5 digits; but the addition of auxiliary tables, called tables of proportional parts, furnishes an easy means of finding the logarithms of numbers consisting of more than this number of digits.

Logarithms of Trigonometrical Ratios. - Tables of these logarithms are used in nearly every problem of navigation.

1. Tables of the Logarithms of Sines, Cosines, Seconts, Coseconts. Tangents, and Cotangents, and Table of Log-haversines.—In order to avoid the inconvenience in calculations arising from the admixture of negative characteristics, in these tables 10 is added to every logarithm. Example— Sin 30° · ½ = '5 · log. sin 30° = 1 698970; the tabular logarithm is 9.698970. When, therefore, one of these tabular logarithms is used in any problem, the result must be corrected by the subtraction of 10. A convenient custom (which we hope to see more generally adopted) is to use the large letter L to indicate the tabular logarithm, while the abbreviation log. is restricted to signify the actual logarithm. Hence log. sin a—Lama 10. The advantage of this rule in obviating all confusion will be apparent in reducing formulæ Example—

$$x = \frac{a \sin a \tan \phi}{b \cos \beta}$$

 $x = \log_a a + (L \sin a - 10) + (L \tan \phi - 10) - \log_a b + (L \sec \beta - 10)$ 

 $\neg \log$ ,  $a + (10 - \log, b) + L \sin a + L \tan \phi + L \sec \beta - 40$ 

=log, a + ar, co, log b + L sin a + L tan  $\phi + L$  sec  $\beta$  40.

Of the same nature as the table of log-sines, log-secants, etc., is the Table of Log-haversines. The log-haversine of an arc is the same as the "log of the square of sine of half the arc," and this is sometimes the heading of the table. Since

hav 
$$\alpha = \sin^{\frac{\alpha}{2}} \frac{\alpha}{2}$$

 $\log$ , hav  $\alpha = 2 \log$ ,  $\sin \frac{\alpha}{2}$ 

L hav 
$$a = 10 = 2$$
 (L sin  $\frac{a}{2} = 10$ )

. L hav 
$$a=2$$
 L sin  $\frac{a}{2}$  = 10.

2. Table of Natural Versines.—This table is used with advantage when an angle or are is required to the nearest second. It is constructed in such a manner as to render it conveniently available in logarithmic computations. To avoid the introduction of negative characteristics, every versine is multiplied by one million. Example—Vers 60°= \( \frac{1}{2} = \frac{1}{2} \); tab. vers = \( \frac{1}{2} \times 1,000,000 = 500,000 \). Here, in the application of logarithms, log vers. 60° \( \frac{1}{2} \) 1698970, but log. tab. vers 60° \( \frac{1}{2} \) 698970. Whenever one of these tabular versines is used in any problem, the result must be corrected for this constant factor of the tables. For an example, see "Auxiliary Angle A." In taking logarithms of tabular versines, the logarithm of 1,000,000 will appear as the correction: for

tab, vers α = vers a × 1,000,000

log, tab, vers a − log, vers a + log, 1,000,000

= log, vers a + 6

∴ log, vers a − log, tab, vers a − 6.

Logarithms, Proportional. Logarithms arranged in tables for inding the fourth term of a proportion, of which the first term (the greatest) is a constant quantity. Let A, a, c, x be the four terms of the proportion of which it is required to find x. Since  $x = \frac{ac}{A}$ , by common logarithms we have  $\log_{x} x = \log_{x} a + \log_{x} c = \log_{x} A$ .

Here four inspections of the table are necessary, and one a ldition and or e subtraction are required in the calculation. But instead of a table of common logarithms, a special table may be formed for the constant A, which requires only three inspections and one addition in the calculation. In equation (1) change the signs and add log. A to each side,

log, A log, r log, A log, a + log, A log, c.

Or if we establish the definition—the logarithm of A diminished by the logarithm of any other number less than A is the proportional logarithm of that number—we have

prop. log x prop. log. a + prop. log. c.

Proportional logarithms are used for interpolating in the tables given in the "Nanticid Almanac". Thus, let it be required to find the time corresponding to a lunar distance found from an observation. The "Nautical Almanac" gives two distances, with the date of each three hours apart, between which our distance lies. Here A 3h, a = the

interval from the first date to the date of our observation, c the change of distance in  $3^h$ , x the change of distance in the interval a. Then, as we want to find a, we have

prop. log. a prop. log. x prop. log. c.

A table for this particular problem, where A 3h, is technically called the Table of Proportional Logarithms; but there are other tables of precisely the same character, and we shall notice them all together. In the "Nautical Almanac" the sun's right ascension, declination, etc., are given for every 24h; the moon's semi diameter, borizontal parallax, etc., are given for every 12h; the lunar distances are given for every 3h; and the moon's right ascension and declination for every 1h. Tables are constructed for each of these cases and inserted in collections of nautical tables under the following titles:—

## 1. Greenwich Date Logarithm for Sun

A=24h. The logarithm of 1440 , the number of minutes in 24h), diminished by the logarithm of the number of minutes in any period less than 24h, is called the Greenwich date logarithm for sun" for that period.

## 2. Greenwich Date Logarithm for Moon.

 $A=12^{h}$  The logarithm of 720 (the number of minutes in  $12^{h}$ ), diminished by the logarithm of the number of minutes in any period less than  $12^{h}$ , is called the "Greenwich date logarithm for moon" for that period.

# 8. Proportional Logarithm.

A =3h. The logarithm of 10800 the number of seconds in 3h), diminished by the logarithm of the number of seconds in any period less than 3h, is called the "proportional logarithm" for that period.

## 4. Logistic Logarithm.

 $A=1^h$ . The logarithm of 3600 (the number of seconds in  $1^h$ ), diminished by the logarithm of the number of seconds in any period loss than  $1^h$ , is called the "logistic logarithm" for that period.

The tables are not now of much practical utility in consequence of the improvement in the arrangement of the "Nautical Almanac."— See Interpolation.

"Logarithm Difference"—Under this heading is tabulated in some works on navigation a quantity used in one of the methods of "clearing the distance" in finding the longitude by a lunar observation. If m and s be the true altitudes of the moon and other body of the observation, m' and s' their apparent altitudes, then

"Log. diff." log. cos m cos s

= $(\log, \cos m + \log, \cos s) - (\log, \cos m' + \log, \cos s')$ ; hence the name. Roper, Table 73.

Longitude (L. longitude, "length") - See Longitude and Latitude

Longitude of an Observer.—The longitude of an observer's place on the earth's surface is the arc of the equator intercepted between the first meridian and the meridian of the observer. Or, which is the same thing, the angle at the pole contained between two meridians, the one passing through a fixed conventional place of reference, the other through the station of the observer. Longitude is measured from the first meridian, and is reckoned eastward and westward either in arc from 0 to 180°, or in time from 0 to 12h. This method, however, gives rise to confusion and ambiguity, and it would be more systematic and convenient if we were to reckon longitudes.

invariably westward from their origin round the whole circle from 0 to 360° 0′ 0″ or 0 to 24h 0m 0s. Longitude and latitude are the co-ordinates for defining the positions of places on the earth's surface.

—See Longitude and Latitude.

Longitude in Arc, and Longitude in Time -The earth rotates uniformly on her axis once in 24 hours, and thus every spot on her surface describes a complete circle, or 360°, in that space of time. Hence the longitude of any place is proportional to the time the earth takes to revolve through the augle between the first meridian and the meridian of the place, and thus the longitude of a place may be expressed either in arc or in time. In reckoning by arc each degree is divided into 60 minutes, and each minute into 60 seconds. In reckoning by time, each hour is similarly divided into 60 minutes, and each minute into 60 seconds. But a distinct notation for each of these has been adopted, degrees, minutes, and seconds being represented by "'", and hours, minutes, and seconds by hims; and care should be observed not to use the same marks for both, great confusion arising from so doing. Longitude in are and longitude in time are easily convertible, for since 360° is equivalent to 24h, 15° is equivalent to lh , lo to 4m , and l' to 4s ,

Longitude (Terrestrial), Circles of.—Great Circles of the terrestrial sphere passing through the poles of the equator, and so called because they severally mark out all places which have the same "longitude." They are also, and generally, called "Meridians," because for every place on the same circle it is noon simultaneously.

—See Co ordinates for the Terrestrial Sphere

Longitude, Difference of (abbreviated, diff. long.). -The difference of longitude between two places is the air of the equator intercepted between their mendians.

Longitude, Difference of, in Time -The difference in longitude between two places as shown by the polar angle between their meridians. This is commonly called the Meridian Distance, and is obtained chronometrically by comparing the errors on local mean time shown by a chronometer at the two places in succession. The error, having been determined by observation at the first station, is corrected by the rate of the chronometer for the interval between this and an observation for the error at the second station; so that the difference of the errors on the local mean time gives accurately the difference of longitude in time between the two places, or their "Meridian Distance." The accurate and systematic measurement of morniam distances is of great importance, especially for determining the long-tude of places previously unknown or uncertain. The chief difficulty of the problem is how to treat the variations of rate between the two observations, so as to produce uniform and consistent results The various methods proposed will be found fully discussed in Shadwell's "Notes on the Management of Chronometers and the Measurement of Meridian Distances "

Longitude from. The longitude of the place suited from.

Longitude in, or to. The longitude of the place sailed to.

Longitude, how found.

### I. IN GEO NAVIGATION

The latitude and longitude at the preceding noon being given, together with the distance i in and the course made and since, and the latitude in having been first found by the aid of the relation. True diff lat. dist. x cos course; the "longitude in " may be found (1) With a table of Meridional Parts, which gives the meridianal difference of latitude; thence,

Diff. long. = mer. diff. lat. × tan course. ∴log. diff. long. = log. mer. diff. lat. + L tan course - 10.

Or (2), By "middle latitude," from the formulæ

dep. = true diff. lat. × tan course.

diff. long. = dep. × sec mid. lat.

∴ log. diff. long. = log. tr. diff. lat. + L tan course

+ L sec mid. lat. - 20.

(2) By "inspection" from the Traverse Table.

Since dist. = dep. × cosec course

diff. long. = dep. × sec mid. lat.

= dep. × cosec (complement mid. lat.);

if the Traverse Table be entered with the given departure and with the complement of the mid. lat. as a course, the distance corresponding will be the diff. long. nearly.

#### II. -- IN CELO-NAVIGATION.

The longitude of a place is measured by the difference between the mean time at the first meridian and the mean time at the place. When the time at the place is the greater, its longitude is E., when it is the less, its longitude is W. Hence the problem of finding the longitude resolves itself into two distinct parts:—lst, The determination of the mean time at the station of the observer—the navigator's "ship mean time," which we indicate by the letters S.M.T.; and 2nd, The determination of the mean time at the first meridian, as for instance that of Greenwich, which we indicate by the letters G.M.T. Different combinations may be made of the several methods of solving the two parts of the problem.

# FIRST PART.—DETERMINATION OF S. M. T.

(I.) One Altitude.—The observation of an altitude of a heavenly body enables us, with the assistance of the known latitude, and of the declination and other elements given in the "Nautical Almanac," to compute the hour-angle H from the formula [See Hour-angle].

L hav H=L sec 
$$d + L$$
 sec  $l - 20 + \frac{1}{2}L$  hav  $(z + l \pm d) + \frac{1}{2}L$  hav  $(z - l \pm d)$ .

The body observed may be either—(1) the sun, (2) a star, or a planet, (3) the moon.

1. When H is the hour-angle of the sun, measured westward from the meridian,

S. M. T. = 
$$H \pm equation$$
 of time.

2 and 3. When H is the hour-angle of any other body than the sun, the mean time being known approximately, the right ascension of the mean sun may be found by adding, to the sidereal time at the preceding Greenwich mean noon, the acceleration for the Greenwich date, Then,

[Before the subtraction of the R.A. mean sun, 24h may be added to or deducted from the sum H+R.A. body, as the case may require.]

(II.) Two altitudes.—The time at the ship for the middle time between two observations for obtaining the latitude ("Double Altitudes") may be found by an extension of Ivory's method proposed by Riddle.—See Latitude, how found; (II.) (III.) ii.

## SECOND PART. - DETERMINATION OF G.M.T.

There are two distinct methods of finding the G.M.T.

- (I.) By Chronometer.—The error of the chronometer on G.M T at a given date and its rate being known, we thence find the G.M T. corresponding to the instant when the observation is taken for determining the S.M.T. This is the most convenient and usual method of finding the longitude at sea.—See Chronometer.
- (II.) By Registered Astronomical Phenomena. -These phenomena take place at the same absolute point of time. Wherever the observer is stationed, the date of their occurrence in G.M.T. is given in the "Nautical Almanac." The principal of such phenomena are-(1) Lunar Distances; (2) Occultations; and (3) Eclopses of Jupiter's Satellites. The only case of this method which is much used at sea is that by lunar distances; it requires no other instrument than the sextant, and when the chronometer is at fault is of very great assistance to the navigator. The longitude may also be determined by finding the increase of the moon's R.A. in the interval between her transit over the first meridian and her transit over the mendian of the observer. This is done by the methods of -(4) Moon Culminating Stars, or, (5) The Moon's Altitude. The former of these methods requires the use of a transit instrument, and therefore cannot be used at sea. We need not notice it further, referring for the explanation of the principle to the "Nautical Almanac" (Appendix -" Moon Culminating Stars"). The latter of these methods is sometimes used at sea, but, though it may occasionally prove of service, the result is very uncertain. The principle is simply this. From the observed altitude the hour-angle of the moon is computed, and from

this together with the S.M.T., her R.A. is obtained, and then, finally, by interpolation in the ephemeris of the moon's R.A. in the "Nautical Almanac," the G.M.T. corresponding to this R.A. may be found.

We shall now further notice the first three methods mentioned of determining the longitude by finding the G.M.T. from the astronomical observations.

1. Lunar Distances - The moon has a very rapid proper motion, sometimes amounting to 15° in 24 hours, and being therefore retarded as regards the diurnal motion nearly an hour on successive days. Her distance, therefore, from the sun, a planet, or bright star which lies in or near to her path, varies very perceptibly in short intervals. The "Nautical Almanac" contains tables of "Lunar Distances" for every third hour of Greenwich mean time, and by interpolation the G.M.T. corresponding to any other intermediate distance of a body tabulated may be found. To determine the longitude at any station on the earth's surface, the observer selects a body whose lunar distance on that day is recorded in the" Nautical Almanac," the preference being given to that body for which the following ratio is the least, Dec. of body - Dec. of moon; a simple practical guide is to take the prop. log , given in the "Nautical Almanac," which is least, because then the body concerned is altering its distance the fistest. He observes the distance, bringing the image (darkened, if necessary) of the brighter of the two objects to the other. This observed distance, the necessary corrections being applied, gives the apparent distance. From the apparent, the true distance has next to be deduced. This operation is called "Clearing the Distance," and its solution is facilitated by various devices. —See Lunar Distance, Clearing.

The true distance being thus obtained, recourse is had to the "Nautical Almanac," and the G.M T. corresponding to this distance taken out by the method of interpolation.

For the purpose of clearing the distance, the altitudes of the two bodies have to be obtained. This is done in one of two ways (1) The altitudes may be observed, at the same moment as the distance, by two assistant observers, and in this case one of the altitudes may be utilized for determining the S.M.T. (2) If more convenient, the altitudes may be computed, the S.M.T. being supposed to be known, the error of chronometer on S.M.T. having been ascertained by some independent observation. This computation may be conducted thus.—If H be the hour-angle of the body, d its declination, and the latitude; then

vers  $z = \text{vers } (l \mp d) + \text{vers } \theta$ when vers  $\theta = \cos l \cos d$  vers H

so that

L hav  $\theta = L \cos l + L \cos d + L \text{ hav H} - 20$ , and log, tab, vers : = tab, vers  $(l \mp d) + \text{tab}$ , vers  $\theta$ 

From the zenith distance z thus found, the true altitude a is known, and hence the apparent altitude a (which is also required, is deduced by inverting the corrections for parallax and refraction

2 Occultations,—The moon in her monthly revolution round the earth passes over every star or other body lying in her path. The immersion of the star behind the body of the moon and its emersion are instantaneous, and can be ascertained without the use of any instrument hable to error. These phenomena, therefore, afford a very accurate means of determining the longitude. The n ethod may be used at sea, the observation being affected by means if a common

kept steadily directed to the moon, but the consequent error in noticing the instant of occultation will generally be inconsiderable. An immersion, when the castern limb is dark, will be the case most easily and distinctly observable. The calculations, however, are long and tedious—See Mr. Woolhouse's paper in "Appendix to Nautical Almanae," 1836.

LONGITUDE.

3. Eclipses of Jupiter's Satellites. - The frequency with which these solipses secur and the easiness of the observation render this method usually available on shore. The diagrams of the positions of the planet and its satellites, as seen in N. latitudes, and other necessary information, are given in the "Nantical Almanac" These figures mus be reversed in S latitude. In taking the observation the following points should be borne in mind: The telescope should have a magnifying power of not less than 40. The sun should not be less than 8° below the horizon, and Jupiter not less than 8° above it. The observer should be ready some minutes before the time the phenomenon occurs, which may be found roughly by applying the ion, trude by account to the time given in the "Nantical Almanac" The disappearances and re appearances happen on the Western side of the planet before opposition, but afterwards on the Eastern side An inverting telescope reverses this. The first satellite is preferable to the others by reason of the greater rapidity of its motion.

The learness of the air, and the power and aperture of the telescope, affer the time of the phenomenon; and the eclipse is not instantaneous the satellite having a considerable apparent dismeter as use from their planet's centre and a penumbra extending to a sensitle, though small, distance beyond the shadow. The only case in which

the observation may be considered complete is, when the immersion and emersion of the same satellite are observed on the same evening with the same telescope and by the same person. The mean of the two results will then give the precise instant of the satellite's opposition to the sun. The method is not practised at sea, in consequence of the difficulty in directing the telescope steadily

Longitude of a Heavenly Body.—The arc of the ecliptic intercepted between the first point of Aries and the secondary circle to the ecliptic, which passes through the place of the body. Or, which is the same thing, the angle at the pole of the ecliptic between the circle of longitude passing through the first point of Aries and that passing through the place of the body. Longitude is reckoned from the first point of Aries eastwardly (in conformity with the direct motions of the heavenly bodies) from 0 to 360°. Longitude and latitude are the ecliptic co-ordinates for defining the positions of points on the celestial concave, and indicating their positions relatively to each other.—See Longitude and Latitude.

Longitude (Celestial), Circles of.—Great circles of the celestial concave passing through the poles of the ecliptic, and so called because they severally mark out all points which have the same "longitude." They are also called "Circles of Latitude," because latitudes are measured upon them.—See Co-ordinates for the Surface of a Sphere.

Longitude, Heliocentric and Geocentric, of a planet. See under Latitude.

Longitude and Latitude (L. longitude, "length"; latitude, "breadth") - Co-ordinates to define the position of a point on a appeare. The extent of a sphere, measuring along a great circle, may

be truly distinguished as the "length," in contrast with the extent measured from this circle either way to its two poles, the "breadth," the magnitude of the former being double the whole of the latter. But these terms are technically used with reference to a particularly great circle, and the use is not the same with regard to the two apherical surfaces with which the navigator and astronomer are concerned. (1) With respect to the carth, that great circle is chosen whose plane is perpendicular to the axis of rotation -the Equator. Taking into account further that the earth is not truly a sphere, but an oblate spheroid, the equator divides it into two uniform parts, and to it all points on the surface hold a similar relation. (2, With respect to the heavens, the apparent path of the sun naturally suggests itself as the great circle of reference, and so "length" of the heavens is reckoned along the Beliptic, and the "breadth" perpendicular to it. To this great circle the other moving heavenly bodles preserve the most uniform relations. It is very unfortunate that the same nomenclature should be in use in geography and uranography l'art of the difficulty thence arising may be avoided in the case before us by always bearing in mind the meaning of the words "longitude 'and "latitude," and that with express reference to the terrestrial spheroid and the celestial concave separately. We must be very careful how we conceive a connection between the circles of the terrestrial and those of the celestial sphere. Though there may be some correspondence or analogy, there is not that connection that at first sight appears. And Lence it would be well if we could avoid describing these circles by the same word, even though this be qualitied with the adjectives "terrestrial" and "celestral;" thus we could wish that the phrases "torrestrial equator" and "celestial equator" fell into disuse, and were supersuded by the simple words "Equator" and "Equinoctial." These answer to each other as do the "meridians" and "circles of declination," but there is no connection between them. If we imagine the plane of the equator and that of the several meridians, these being all fixed circles of the earth, to be extended till they cut the celestial concave, the great circles in which they intersect it will not be fixed circles of the heavens, but revolve or sweep over its face diurnally. The great circle corresponding to the equator (in which it must be remembered is situated the origin of the ordinates reckoned on it) would revolve in its own plane, and the great circles corresponding to the meridians would move perpendicularly to their own planes with the daily rotation of the earth. It is evident, then, that the position of a point in the heavens cannot be defined by referring it to such great circles. But great circles may be conceived for this purpose analogous to the above, but differing from them in this that they remain stationary and fixed in the heavens, quite independent, therefore, of the geographical position of the observer. The great circle of the heavens which thus answers to the equator on the earth to called the equinoctial; and the great circles of the heavens perpendicular to it and answering therefore to the meridians of the earth, are called circles of declination. Arcs of these circles, used as co-ordinates to define the position of a point in the heavens, are very properly not called by the same names (longitude and latitude) as those which designate arcs on the corresponding circles on the earth's surface, but have the distinctive terms applied to them of "right ascension" and "declination." This is well; but worse confusion has been introduced by the early astronomets using the terms "longitude" and "latitude," already appropriated by the geographer, and that to describe arcs of altogether another system of co-ordinates

Their reason for their choice of these words in of the heavens. explained above; but the unlucky device is a source of difficulty to the young student and of inconvenience to all. Sir John F. W. Herschel, after speaking of the terms in their terrestrial sense, says on this point: "It is now too late to remedy this confusion, which is engrafted into every existing work on astronomy. We can only regret, and warn the reader of it, that he may be on his guard when we shall have occasion to define the use of the terms in their releation sense, at the same time urgently recommending to future writers the adoption of others in their places." The necessity of combining, for the moment, terrestrial and celestial great circle co-ordinates is met by the device of a system of polar co-ordinates, all the elements of which have reference to time. The initial line is the "celestial meridian" (or "noon circle"), the radius vector is the "hour-circle," and the polar angle the " hour-angle." -- See Co-ordinates for the Surface of a Sphere; and Triangle, Instantaneous.

Longitude and Latitude (Terrestrial).—Co-ordinates for defining the positions of places on the earth's surface. Longitude is measured on the equator from the intersection of it by the first meridian, and is generally reckoned eastward and westward from 0 to 180°; latitude is measured on the meridians from the equator to the north the south poles from 0 to 90°—See Co-ordinates for the Terrestrial Sphere.

Longitude and Latitude (Celestial).—The ecliptic co-ordinates for defining the positions of points of the celestial concave, and indicating them relatively to each other. Longitude is measured on the ecliptic from the first point of Aries castward from 0

to 360°; latitude is measured on circles of latitude from the ecliptic both ways from 0 to 90°.—See Co-ordinates for the Celestial Sphere.

Loxodromic Curve (\lambda of \delta s, "alanting"; \delta p\delta uos, "course").—
"A curve which cuts at a constant angle all the lines of curvature of a surface which belong to one and the same system." This is the general definition. A particular case is found on the earth's surface in the Rhumb curve which makes a constant angle with the meridians.

—See Equiangular Spiral or Rhumb Line.

Lubber's Point.—The mark on the inside of the compass case indicating the direction of the ship's head. When the box containing the compass is properly fixed in its place, the line joining the centre of the compass-card and the lubber's point is fore-and aft, or parallel to the keel of the ship. The derivation of this compound word is frequently a subject of discussion. The expression is generally connected with "land-lubber," the contemptuous name seamen use for any awkward clumsy fellow without intelligence or activity. Such a one would slavishly require the aid of this point in steering, whereas a helmsman who was a seaman would more truly strike a fore-and-aft line with his eye; just as in going aloft the former would require the "lubber's hole," while the latter would mount by the futtock shrouds. It is best, however, to fall back, for its significance, upon what is doubtless the root of the word. To "lob" is found in Shakespeare, meaning "to let fall heavily," and the old English "lob," Welsh "llob," means "a dull sluggish person." Probably the "lubber's point" was originally called the "lob-point." In the earliest azimuth compasses, there were four of these small black lines, corresponding to the quadrantal divisions of the circle, which remained fixed with the ship, while the compass-card appeared ic move in a lively manner. This card was then significantly called the "Fly"—See Compass, Steering

Lunar (L. luna, "the moon").—Pertaining to the moon. Thus we have the Lunar Month, the Lunar Day portions of time defined by the motions of the moon; Lunar Eclipses, Lunar Distances, etc.

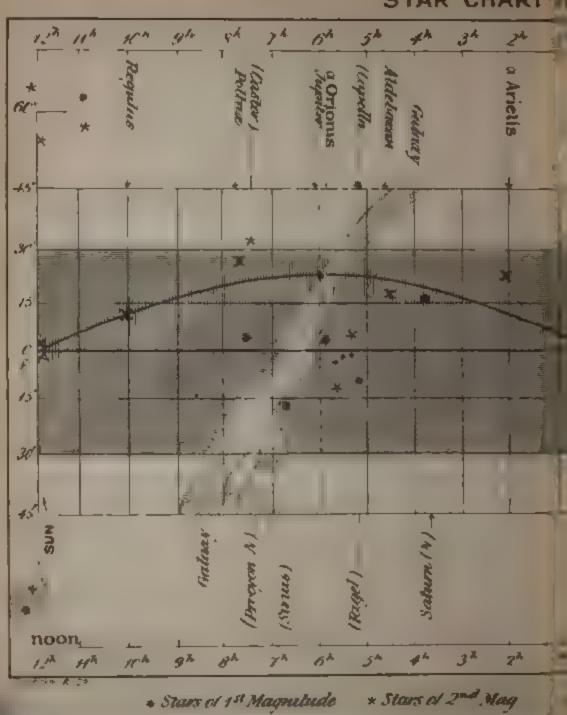

Lunar Distances.—The moon having a very rapid proper motion, her distance from other bodies which lie in her path varies very perceptibly in short intervals. Hence these distances have been made the foundation of one of the most important methods of detormining the longitude at sea. [See Longitude] In the "Nautical Almanac" are registered for every third hour of Greenwich mean time the augular distances of the moon's centre from certain bodies, such as they would appear to an observer at the centre of the earth. When a lunar distance has been observed at any station on the surface of the earth, and reduced to the centre by clearing it of the effects of parallax and refraction, the Greenwich mean time corresponding to this true distance can be found from the tables by the method of interpolation.

In observing a distance, the general rule is—Bring the image (darkened by shades, if necessary) of the brighter of the two to the other object seen directly.

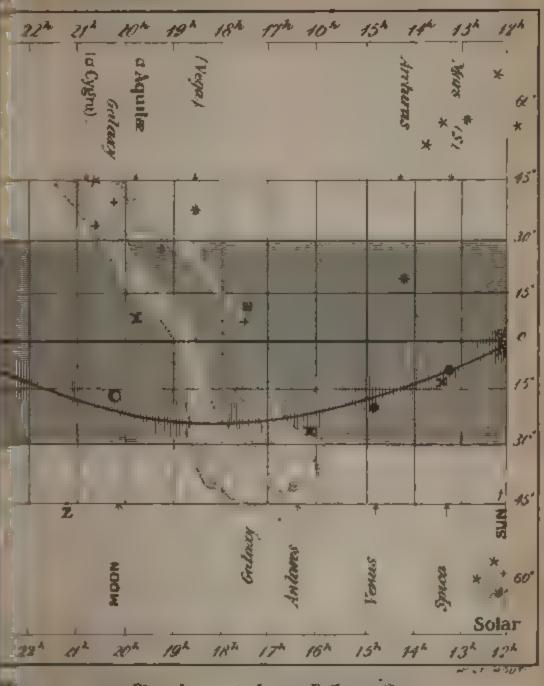

Lunar Distance Bodies.—Bodies whose distances from the moon are calculated beforehand and tabulated in the "Nautical Almanac," pp. x111.—xv111. of each month, for the determination of the longitude. They are fourteen in number, viz: the sun, the four planets, and nine fixed stars

# STAR CHART

# R DISTANCES.

ocroPlands.

x Lunar Distance Stars.

......

f

1. The inclination of the moon's orbit to that of the earth is about 5°9'; honce, the moon's latitude never exceeds this amount N. or S., and, although her actual path in the heavens is a very irregular curve, she is always to be found within a belt of about 10° 18' broad which is bisected longitudinally by the ecliptic. Of the four planets used in lunars, the path of Venus has the greatest inclination to the ecliptic, viz: about 3° 24'; hence all these bodies, are found always within this belt. It was a belt of this kind, 8' or 9' on each side of the ecliptic, that was called by the socient astronomers the Zodiac.—See Zodiac.

Referring the sun, moon, and planets to the equinoctial. The obliquity of the ecliptic being about 23° 27', the sun is always found in a zone, 46° 54' broad, bounded by the tropics; the moon is always found in a zone, 57° 14' broad, bounded N. and S. by the parallels of declination 28° 36 (23° 27° + 5° 9'); and the four planets are also well within the same zone. Of the fixed stars used in lunars only one, Fomalhaut, has a declination slightly exceeding 30°. We may therefore consider that all the lunar-distance bodies are comprised within an equatorial zone 60° broad.

In the accompanying chart we have given the regions of the beavens from the equinoctial to 45° N. and to 45° S. declination, thus comprehending a zone of 90° broad. The lunar-distance zone of 60° broad is shaded horizontally; and in this the ecliptic is drawn with its accompanying lunar and planetery belt of about 10° broad, shaded vertically.

2. The motions in right ascension of the sun, moon, and planets are all subject to irregularities; but the change in the moon's right ascension is much more rapid than that of any of the other bodies

that have a proper motion. Hence the admissibility of the sun and planets as lunar-distance bodies. A general idea of the ratio of the motion of the moon to that of the sun will be best obtained by comparing their sidereal periods. The moon completes a revolution of the celestial concave in a Sidereal Lunar Month, the mean length of which is 27:322 mean solar days; the sun completes a revolution of the celestial concave in a Sidereal Year, the mean length of which is 365:256 days. The proper motion of the moon in the heavens is therefore about 13; times more rapid than that of the sun. To guard against confusion it is important that the student should remark that a complete sidereal revolution is here called in the case of the sun a "year," and in the case of the moon a "month."

In the chart we have inserted the sun, ②, in the autumnal equinox (a. R.A. 12h), and placed the moon and the planets in their proper positions for this date, September 22nd, 1882. The moon, ①, is two days after her first quarter, in R.A. a little after 20h and declination about S. 15°. The planets, O, are placed according to their positions for September 22nd, 1882, given in the following table.—

	Symbo	ol, Inclination	RA.	Dec	
Inferior Planet	Venus 9	3' 23	14h 52m	19* 42'	
	(Mars &	1° 51	13h 26m	8* 50'	
Superior Planete	Jupiter 2	1* 19	6h 1m	+ 22° 58′	
	Saturn h	2* 30	3h 37m	+ 16° 58'	

3. Fixed Stare.—The fixed stars used as lunar-distance bodies are the nine, particulars of which are given in the following table. They are userted in the chart and distinguished by the symbol )(.

	Mag.		R.A.	Dec.		
1. (Hamel) a Arietis	2	24	Om 36s	+ 22° 54′ 32″		
2. Aldeburan (a Tauri)	1	4h	29m 13s	+ 16* 16' 21*		
3. Pollux (\$ Geminorum)	1.2	7b	38m 9s	+ 28' 18' 22"		
4. Regulus (a Leonie)	1.2	10h	2m 7s	+ 12° 32′ 22″		
5. Spica (a Virginis)	_ 1	13h	19m 1s	10° 32′ 52"		
6. Antares (a Scorpii)	1,2	16h	22m 13s	26° 10′ 11°		
7. (Altair) a Aquile	1.2	19h	45m 5s	. + 8° 33′ 51″		
8. Fomalhaut						
(a Piscia Australia	) 1.2	22h	51m 12s	30° 14′ 26*		
9. (Markab) a Pegasi	2	22h	58m 57s	+ 14" 34" 44"		
We have not complicated the chart, introduced to illustrate						
lunar-distance bodies, by crowding it with many other stars. All						
stars however of the first magnitude, within declinations 45° N. and						
45' S., are inserted, and a few constellations useful as position-guides						
are given, the names being						
the equatorial regions, are Pegasus and Orion. The Galaxy is also						
depicted as being a useful natural guide on a bright night.						

4 With reference to Diurnal Time the zero circle of right ascension 0.70 is coincident with the meridian of Greenwich at aidereal noon at Greenwich. On the date represented in the chart, solar time at Greenwich is midnight: and Z will represent the zenith of a place in latitude 45° S. and longitude 40° W., the time at this place being between 9h and 10h p.m. The bodies given in the "Nautical Almanac" for this date, with their distances are:—

Antares	4-1	164	W	53*	29	41"
Fomalhaut	84×	***	E	40°	12	5"
а Редазі	***	994	E	51°	44'	45*
a Arietis	***	100	E	94*	14'	47"

The chart accompanying this article is necessarily on a very small scale, and is intended only for explanation. The young officer is strongly advised to draw a chart on a larger scale, and himself insert the different bodies, the fixed stars being put in ink and the other bodies in lead pencil. On such a chart he may also approximately project his zenith. If it is objected that this will not suffice for a problem in the practical solution of which extreme accuracy is essential, we would urge that a rough solution is frequently invaluable both as an aid for grasping the principle and as a safeguard against any fundamental error being introduced by an oversight.

Lunar Distance, Clearing the.—The operation of deducing the true from the apparent lunar distance. This problem is effected by the solution of two spherical triangles having a coincident angle subtended by the two distances. The three sides of one of these triangles being given, this angle may be found; then in the other triangle, two sides and the included angle are known to determine the third side, the true distance required.

Let M and M' be the true and apparent places of the moon.

d ,, d' ,, distances.

z the true zenith distance of the moon.

In the triangle M'ZS' other body.

$$\cos^2\frac{Z}{2} = \frac{\cos S \cos (S - d')}{\cos m' \cos s'}$$

Where, 
$$S = \frac{m' + s' + d'}{2}$$

Again in the triangle MZS

Sin 
$$\frac{d}{2} = \sqrt{\cos\left(\frac{m+s}{2} + \theta\right)\cos\left(\frac{m+\theta}{2} - \theta\right)}$$
  
Where,  $\sin\theta = \sqrt{\cos m \cos s \cos^{2}\frac{Z}{2}}$ 

- I. The above formulæ require only the ordinary tables of log sines and log cosmes. The calculation may be facilitated by the adoption the following artifice:—Take m', s', and d' to the nearest innute half minute, rejecting the odd seconds, and the logarithms required in their be taken out by inspection exactly from the tables. Iterwards increase m and s by as many seconds as have been beeted from m' and s', and add to d the seconds reserved from d',
- 2. The work is much facilitated by the use of special tables giving the value of a subsidiary angle for different arguments.

In the preceding formulæ combine the expressions for sin  $\theta$  and  $\cos^2 \frac{Z}{2}$  thus—

Sin 
$$\theta = \sqrt{\frac{\cos m \cos \theta}{\cos m \cos \theta} \cos \theta \cos (5-d)}$$

Where  $\log \frac{\cos m \cos s}{\cos m \cos s} =$ " Logarithmic Difference" = log (2 cos A).

- (a) The "Logarithmic Difference" is given in Raper's Tables, and may be used with the ordinary tables of log sines and log coines.—See Logarithmic Difference.
- (b) The "Auxiliary Angle" (A) is given in Inman's Tables, and sy be used very conveniently in conjunction with a table of versines. he formula embodying the operation is—

Tab vers d = tab vers (s + v) + tab vers (d' + A) + tab vers  $(d' \sim A) + tab$  vers (m' + s' + A) + tab vers  $(m' + s' \sim A) + tab$  vers  $(m' + s' \sim$ 

3. Airy's Method —A method of clearing the distance was devised by Sir G. B. Airy depending on the use, in the factors of corrections, not of each apparent element nor of the corresponding corrected element, but of the mean between the two.

The elements which we require are: the apparent altitude and the corrected altitude of the moon, the apparent and the corrected altitude of the sun, and the apparent and corrected distance. The first five of these are known accurately. The last (the corrected distance between the sun and the moon) must be estimated. There is no difficulty in doing this, with accuracy abundantly sufficient for this investigation. With Greenwich time by account, the distance may be roughly computed from the distances in the "Nautical Almanac." Or without time or calculation, a navigator accustomed to lunar distances may form a shrewd guess of the probable amount of correction. We have now all the six elements required for the investigation.

Let Moon's corrected attitude + moon's apparent altitude 2 A;

Moon's corrected altitude - moon's apparent altitude = 2 a;

Sun's apparent altitude + sun's corrected altitude = 2 B;

Sun's apparent altitude - sun's corrected altitude = 2 b; Corrected distance + apparent distance = 2 C; Corrected distance - apparent distance = 2 c;

Sun's apparent altitude A - a; corrected altitude A + aSun's apparent altitude B + b; corrected altitude B - b; Apparent distance B - c; corrected distance B - c.

the essential circumstance which directs the further investigation is equality of the zenithal angles, and consequently of the cosines of zenithal angles. The corresponding equation is—

$$\frac{\cos (C - c) - \sin (A - a) \cdot \sin (B + b)}{\cos (A - a) \cdot \cos (B + b)} =$$

$$\frac{\cos (C + c) - \sin (A + a) \cdot \sin (B - b)}{\cos (A + a) \cdot \cos (B - b)}$$

this equation may be reduced and simplified by neglecting terms inich do not affect the practical accuracy of the result. It thus becomes—

marking that 2a, 2b, 2c are the corrections of moon's altitude, sun's titude, and distance; the result of the equation is—

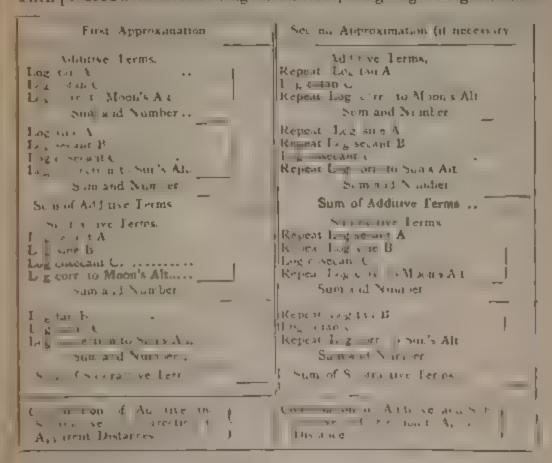

The only opening to error in this formula is in the estimated value of C, as depending on error in the estimated "Nautical Almanac" distance, or in the estimated correction to the observed distance. Suppose that the time by account was 4m in error (implying error of 1° in longitude). The approximate correction of distance would be taken out about 2' in error, and C would be about 1' in error. If the value of the distance was about 60°, an error of 1' would produce in cotan C an error of about 1'100 of that term of the computed correction, and in cosec C the error would be 5000. These would be hardly sensible. But if with C corrected by this approximation, the calculation be repeated (requiring only a few minutes), the error of result will be totally insensible.

The above is extracted from Airy's brochure, published by order of the Lords Commissioners of the Admiralty in 1881. He gives a form for use in working examples which is appended.

Prepare this Table, inserting numbers instead of the printed words.

Correction of Moon's Correction to Stan's Apparent Abstance Apparent Abstance Apparent Abstance Apparent Abstance Sun's Apparent Abstance A tode A tode A tode Sun's Corrected A tode A tode  Sun's Apparent Abstance Corrected A tode A tode  Sun's Corrected A tode  Sun's Corrected Distance Corrected Distance  Corrected Distance  Sun's Corrected Distance Corrected Distance  Sun's Corrected Distance Corrected Distance  Sun's Corrected Distance Corrected Distance  Sun's Corrected Distance
---

## Then I roceed with the following calculations, using 5 figure-logar, thms

This form supposes that C is less than 90°. When C exceeds 90, the supplement to 180° is to be taken, the cosecant and cotangent of that supplement are to be used, and the signs of the first and forth numbers, which are produced by cotan C are to be changed; the first number will become subtractive, and the fourth number a littive.

The second approximation will very rarely be required. If, however, the final "Correction to Apparent Distance" differ from

that assumed at the beginning by 2' or 3', it may be satisfactory to use the second approximation; it is very easy.

Lunar Observation.—The "Lunar Observation" is the name by which is distinguished the important observation of a lunar distance for determining the longitude

Lunation. The "Lunar Month," or, as astronomers call it, the "Moon's Synodical Period." It is determined by the recurrence of the moon's phases, and is reckoned from new moon to new moon it. from leaving her conjunction with the sun to her return to conjunction. In consequence of the sun having a proper motion in the heavens in the same direction with that of the moon, the latter body, after leaving the sun, will have more than a complete circle to perform in order to come up to the sun again. Hence a lunation exceeds the moon's aidereal period; its mean length is calculated to be 294 125 44 o 2 87s.

Lunitidal Interval. -Of the tides,—the interval between the moon's transit and the high water next following. It varies from day to day during the fortnight between new and full and full and new moon. The lunitidal interval must not be confused with the "Retard" or "Age of the tide."

Lyra (L. "The Lyre").—A constellation to the south of Drace and Cygnus—It contains one bright star a Lyra, also called V-ya. This may be found by its being situated at about the same distance from the pole star on one side as Capella is on the other, and by its propriequity to the conspicuous pair of the Dragon. Mag. 0.2; N A. 1896, R.A. 18h 33m, Dec. +38° 41′

M

m. -Of the letters used to register the state of the weather in the log-book, m indicates "Misty or Hazy—so as to interrupt the view."

Magnet. Magnets are substances (chiefly iron, in some form) whose particles have assumed a certain condition called *Polarity* connected with definite directions governed by terrestrial influence. A magnet when freely suspended by its centre of gravity spontaneously assumes a definite position relatively to the earth, one end or pole pointing towards the north, and dipping downwards in northern latitudes, the other end or pole pointing towards the south, and dipping downwards, in southern latitudes. This condition of polarity magnets communicate to like substances having the same tendency, when in their vicinity, by a process called *Induction*, and an attractive power is developed. When two magnets are in propinquity, unlike poles attract each other and like poles repel each other. Magnets are either natural or artificial.

(1.) Natural Magnets.—The earth as a whole is the great natural magnet. Some natural ores of iron are susceptible of terrestrial induction, especially one combination, which retains its magnetic polarization tenaciously. It consists of the protoxide and the peroxide of iron with small portions of silica and alumins. As blocks of this substance have lain for ages in the same position with regard to the magnetic line of force of the earth, they have acquired magnetic polarity; they have become natural magnets, and fragments when removed from the stratum in which they are found assume an independent polarity according to the laws of magnetism. This natural magnet is usually of a dark grey has with a dull metallic lustre, and is found in the iron mines of many countries. It was

anciently obtained chiefly from Magnesia in Asia Minor, and hence the word "magnet." Its other names are interesting. The people in Pliny's time called it ferrum vivum, "quick from"; the Chinese know it as tchu-chu, "the directing stone"; and similarly in the Swedish it is sepel sten, "the seeing stone"; in Icelandic, leiderstein, "the leading stone"; and in English the leadstone or loilestone (from Sax lerden, "to lead"). Many gems also, and the metals cobalt and nickel, give signs of magnetism.

(II). Artificial Magnets Bars of steel to which magnetic polarity has been communicated by artificial means. Iron is technically distinguished as "soft" and "hard "iron according to its magnetic qualities "Soft non" becomes instantaneously magnetised by induction when exposed to any magnetic influence, but has no power of retaining any permanent in lependent magnetism; "hard fron " is less susceptible of being inagnetised by induction, but when once magnetised retains its magnetism permanently. "Hard iron" may, however, be of variable hardness, and no uniform standard of magnet a power can be ascribed to it, nor do we always know whether we have really "hard" from The description of hard from known as "steen," is employed to make artificial magnets. Steel is iron with a definite amount of carbon combined with it, and it may be made almost of one uniform kind; consequently, by its use we obtain ninguets the permanency of the known power of which is assured and can be trusted. The steel har magnets, used for correcting compasses, are made of very hard steel, those of Sir William Thomson being of " \_lass hardness,"

Magnets may be made by three different kinds of methods: by utilizing the magnetic influence of the earth, by the application of another magnet, or by electro magnetism. (a) When a bar remains

long in the direction of the magnetic meridian and dip, its particles acquire the magnetic polarity; and this process can be hastened by any means which facilitates a change of condition among the particles, such as heating succeeded by sudden cooling, the transmission of an electric discharge, or percussion. (b) Simple juxtaposition, in a line, end to end, with a bar magnet will convert a bar of iron into a magnet. The energy is doubled by the bar being placed between two magnets in a line, conterminous with their opposite poles. The process may be accomplished by the aid of friction, either by drawing one magnet along the whole length of the bar; or by using two magnets in a manner called "double touch," in which the dissimilar ends of the two magnets, held obliquely, are made to slide from the centre of the bar to its extremities, this being repeated several times (c) A cylinder of iron may be converted into a magnet by passing an electric current through a metallic wire code I round it at right angles to its axis.

A knowledge of the above facts is important to seamen. On board ship the stanchions, iron spindles, etc., often become magnets (especially in men-of-war, where the vibration is great from the firing of the gune) and then they cause a more permanent deviation of the compass that they did in their unmagnetised state. Again, it would be possible for a castaway scaman to extemporise a magnet out of a piece of ramfod by holding it approximately in the position of the line of magnetic force and striking it with several smart blows. [See Magnetism, Terrestrial] And, finally, by bearing in mind the facts of magnetism, those who have the care of the scaman's best though very susceptible friend will know now to preserve his constancy. The same mechanical means which dove lop magnetism will also destroy it in a bar placed oppositely or transversely to its

natural magnetic position. Thus a needle may lose its power by a fall on a hard substance. Again, spare compass-cards should be kept in cases constructed with a view of keeping poles of the same name from being placed together. According to their form, artificial magnets are classed as "bar magnets," "horse-shoe magnets," "compound magnets," etc.; but the most important practical modification is the magnetic needle.

## Magnets; Permanent, Transient, Sub-permanent.-

- (I.) A permanent is a true magnet which possesses in itself an independent centre of force or system of forces similar to that exerted by the earth; and it does not part with this power. A permanent magnet is composed of "hard iron," a description to which steel belongs.
- (II) A transient is an induced magnet, one which is dependent for its magnetism upon the proximity of another external magnet, whether this be the earth itself or a true artificial magnet nearer to it. Its magnetism is movable or unfixed, the manifestation of it depending, at any instant, on the position of the bar relatively to the earth or influencing magnet. Such magnets are formed in "soft iron" (wrought and cast iron) not subject to any special violence
- (III) A Sub-permanent is a temporary true magnet -one which has the character of a permanent magnet, possessing an independent centre of force or system of forces, but parting with this power after the lapse of some time. This condition takes place in "soft iron" which, while under the influence of induction, has been thrown into a state of tremor from mechanical violence. Such a true magnet parts with the greater portion of its magnetism by the gradual action of terrestrial induction.

Magnetic Needles. — A light bar or thin cylinder of magnetised steel adapted for suspension is called a magnetic needle. If poised on its centre of gravity and free to assume any position, its direction indicates the line of magnetic force of the earth at the place. But the forms of mounting with which we are here principally concerned are two, in which the needle is constrained to move in definite planes.

- I The Horizontal-plane Needle is one which is placed on a pivot, and so balanced by compensating weights that it moves only in azimuth. It is technically called The Declination Needle, and by seamen it is known as The Variation Needle. It indicates the angle which the magnetic meridian makes with the geographical meridian of the station. The declination is called east or west according as the marked end of the needle is drawn to the east or west of the meridian.
- 2. The Vertical-plane Needle is one hanging on a small horizontal axis and capable only of moving in altitude. It is technically called The Inclination Needle, but is more commonly known as The Dipping Needle. It indicates the angle which the line of magnetic force makes with the horizon. The inclination is called Positive or Negative according as the marked end of the needle inclines below or above the horizon.

Magnetic Needle, Astatic. -A magnetic needle withdrawn from the action of terrestrial magnetism, and therefore having no stational position of equilibrium with reference to the earth. It is of use to exhibit strikingly the effect of one magnet on another.

A single magnet may be rendered astatic by placing the axis on which it is movable in the direction of the magnetic dip; its motion will then be in the equatorial plane, and in this it will rest in any position.

The most convenient form, however, is a combination of two meedles of equal power fixed in a frame one above the other, with apposite poles super adjacent, and poised on a fine pivot. The united notices mutually neutralize the terrestrial magnetism on each, to which the whole together is thus rendered insensible. Each magnet however will be separately affected by the local attraction of another magnet brought near it, and each may be used as an "astatic read e"

Magnetic Needle, vibrating -The relative magnitudes of the terrestrial magnetic horizontal force at different parts of the earth may be ascertained by observing the vibrations of the same magnet at these localities. Such a needle may also be used to find the relative magnitude of the horizontal component of a ship a magnetism. It is an essential instrument to the compass adjuster. The force is inversely as the square of the time occupied by each vibration; therefore the comparative intensities of the forces causing the vibrations are in the ratio of the squares of the number of vibrations made in a given period of time

A vibrating needle should be specially adapted for the purpose. It need be no more than three inches long, and it is convenient to prepare it so as to vibrate thirty times a minute when on shore and removed from the influence of all local disturbance. It may be suspended horizontally by a few fibres of ailk. Those used in the Royal Navy vibrate on a special pivot which fits the vibrating box on shore and the compass bowl on board, and the pivot used on shore must be used on board.

# Magnet Needle; Axis, Neutral Line, Poles.

A.c.s.—The direction of the magnetic polarization of the needle.
 This should coincide with the longitudinal line of the needle itself,

otherwise the needle of the mariner's compass will not point with exactness to the magnetic north and south. At the Admiralty Compass Observatory the essential quality of coincident axes is made a point of special examination in all compasses, and the needles are placed with their edges on the card partly with a view to ensuring this result.—See Compass, Imperfections, Adjustments, Errors

- 2. Neutral Line —A line passing across the surface of the bar transversely to its length, in which will be found the points where the magnetic force is zero. If the bar has been carefully magnetised this will be at its centre
- 3. Poles.—The two points in which the attractive and repulsive power of the magnet appear to be concentrated. The distance of each pole from its end of the bar is about it of the whole length. That pole of the compass needle which points to the earth's magnetic north is commonly called the "North Pole" of the needle for that reason, and the other the "South Pole" But these terms are objectionable as seeming to imply that like poles attract each other, which is the reverse of the truth. Hence it has been suggested to distinguish the pole of the bar which points to the North pole of the earth as the "Marked," and the other as the "Plain," end. Astronomer Royal Sir (a. B. Airy adopts the convention of calling the magnetism of the earth's northern regions "Plue," and that of the southern "Red," and, as unlike poles attract each other, the end of a needle pointing to the north would be the "Red" end and the other the "Blue."

Magnetism, Terrestrial.—The magnetic influence of the earth, indicated by the lifterence and changes in magnetic plei cinema observed on different parts of its surface. In treating of this force

we must consider its direction and its intensity, and in addition to these, the distribution of its effects over the surface of the globe, and what changes it is subject to. The distribution will be noticed under the heads of its direction and intensity, being represented in each separate case by a system of imaginary lines on the earth's surface; the changes will be noticed subsequently.

- 1. The Direction of the Force of Terrestrial Magnetism is estimated in two co-ordinate planes, the one horizontal the other vertical, in the former of which the geographical meridian is taken as the initial line, in the latter the horizontal plane is the origin. It is measured by the direction of magnetic needles suspended to move in each of these planes; the needle hung so as to move in the horizontal plane is called the "Declination" or "Variation needle," that hung so as to move in the vertical plane, the "Inclination" or "Dipping needle."
- the angle which the direction of the declination needle, called the "magnetic meridian") makes with the geographical meridian. Imaginary lines on the earth's surface passing through all points where the needle points due north and south, are called Lines of no Variation; and lines passing through all points where the needle is deflected from the geographical meridian by the same amount, are called Lines of Equal Variation, or Isogonic Lines. These are extremely irregular curves, and form two closed systems surrounding two points which may be called the Centres of Variation. One of these points is in Eastern Siberia, the other in the Pacific Ocean, in the vicinity of the Marquesas. The Isogonic Lines all converge to one point in the northern part of North America, Sic James Ross.

Magnetic Pole: there is a similar convergence to a point in the Antarctic region to the southward of Australia which is the South Magnetic Pole.

- (ii.) The Direction in the Vertical Plane. This is measured by the angle which the inclination needle makes with the horizon points on the earth's surface, or rather in two small linear spaces, the needle assumes a position perpendicular to the horizon, one of its poles being downward in one hemisphere, and the opposite one in the other hemisphere. These two spots are called the Magnetic Poles. At the north magnetic pole, the "marked" or "red" pole of the needle dips; at the south magnetic pole, the "plain" or "blue" pole of the needle dips. The positions of these poles are lat 70° N , long. 97° W, and lat. 73° S., long 147° E. Encircling the earth is a line on every point of which the needle remains horizontal, so that there is no dip; this line is called the Magnetic Equator. It crosses the terrestrial equator in several points, and never recedes from it on either side further than 16°; the position of the two being nearly coincident in that part of the Pacific where there are few islands, and most divergent when traversing the African and American continents. Intermediate to the poles and equator, lines are drawn through all points where the needle makes the same angle with the horizon. These are called Lines of Equal Inclination or Dip, or Isoclinal Lines.
- 2. The Intensity of the Force of Terrestrial Magnetism varies in different parts of the earth as the square of the number of vibrations which the magnetic needle freely suspended makes in a given time. There are four points on the earth's surface where the magnetic force is a maximum, two in each hemisphere, those of the greatest intensity lying in the southern hemisphere. These points are called the Foci of Maximum Intensity. The northern foci he the one in Hudson's

Bay, the other in Northern Siberia; the southern foci, one very near the other in the South Pacific, south of Tasmama; there is some doubt as to the existence of the second southern focus. An arregular curve, encircling the earth, is drawn through that point in each meridian on which the magnetic intensity is least; this is called the Dynamic Equator. The force is of unequal intensity in its several parts I his equator is considered by some authorities to be the true line of separation between the northern and southern magnetic hemispheres. Again, intermediate to the feet and equator are lines. passing through all the points where the magnetic intensity is the same; these are called Lines of Equal Majnetic Intensity, or Isodynamic Lines. In each hemisphere they first form a series of ovals round each of the foci there actuated, having their major axis in the line joining the two foci. At a greater sweep a pair of these ovals join, and form a figure of to, and exterior to this single curves encompass both foci. These are first much inflected towards the point of junction, but become more regular as they approach the dynamic equator.

Terrestrial magnetism is influenced by causes which render its phenomena subject to time-changes affecting both its direction and intensity. This term "variation" is applied to all those, but we would prefer a word not already appropriated by common usage to a special use, and suggest "Fluctuations." There are Secular Fluctuations which take ages to run their course, and the causes of which are as yet unknown. Thus in London, previous to the year 1660, the needle is recorded to have had an eastwardly declination; subsequently it was found to have diverged to the westward, attaining its maximum of 24° 30′ W about 1819, and then gradually returning towards the meridian again. At present it is about 17° W, and it is

decreasing at about the rate of 8' annually. Similarly the dip has been decreasing at London for the last fifty years at the rate of 3' annually. We must here remark that our most recent observations tend to prove that the magnetic poles do not move, and of the motion of the foci of intensity we have no data to go upon. The great foci of magnetic change he between North Cape of Norway and Cape Horn. There are also Periodic Fluctuations, which run through their course in ascertained periods, and which can be traced to their causes. Both the direction and intensity of terrestrial magnetism are influenced through the course of the year by the motion of the sun in the ecliptic, and they fluctuate with the declination of the moon and her distance from the earth. Again, there is the Horary or Diarnal Fluctuation, which, like the tides, goes through its changes twice in the twenty-four hours. Thus in the middle northern latitudes the N. pole of the declination needle has a mean motion from east to west from 8 A.M. to lik P.M.; it then returns to the east till evening, when it makes another excursion to the west, returning to its original position by eight o'clock in the morning. The angular extent of the excursion is greater in the day than in the night, in summer than in winter. In the middle latitude of Europe it is 13 or 14'; on the equator, where it is very regular, 3 or 4'. The phenomenon is reversed in southern latitudes. Once more, there are Transcent Perturbations of terrestrial magnetism Vast magnetic storing occur at irregular intervals, covering extensive areas of the globe. Earthquakes, electric changes, the aurora borealis, agitate the magnet, and disturbances synchronous with the appearance of solar spots have been observed.

Observations of terrestrial magnetism have for their object the determination of the above elements. Ships are supplied with

instruments both for absolute and relative measurements, the latter being all 'hat are possible at sea, while the former furnish base stations. Directions for the use of these instruments are given in a Paper by General Sir E. Sabine, in the Admiralty "Manual of Scientific Enquiry." The results of such observations are embodied in charts and tables. [See article, "Terrestrial Magnetism" in "Elementary Manual for Deviations of Compass."]

Magnetism Charts.—There are three magnetism charts corresponding to the three classes of phenomena referred to above, viz. those exhibiting the isogenic, the isoclinal and isodynamic curves. The epoch for which these charts are constructed, and to which all observations used should be reduced, ought to be definitely stated, as all the elements they embody change with the lapse of time.

(I.) Chart of Lines of Equal Magnetic Variation. - An inspection of this chart will give a good general view of the arrangement of the isogonic lines. The "Magnetic Meridian" of any place is given by the chart; the lines of no declination being the loci of places with no declination. These agonic lines cross the geographical equator at about 75' east and 48' west longitude. The surface of the globe is divided into two unequal regions by the agonic meridians, in the smaller of which, the Atlantic area, the variation is westerly; and in the larger, the Pacific area, the variation is easterly convergence to the two magnetic poles will be observed. This chart is most useful in the ordinary practice of navigation When the total error of the compass has been found by astronomical observations, that part due to the declination or variation may be taken from the chart, leaving the remainder, which arises from the deviation of the compass. It thus furnishes, in these days of from ships a most needful means of checking, at any time and place, the Table of

Deviations. This chart may also warn the navigator beforehand where the changes in the variation are most perplexing and dangerous, as where the lines are crowded together and he athwart the usual tracks of ships, spots which happen to be the most frequented centres of maritime enterprise. So important is this chart, that one of them on Mercator's projection and on a large scale, smbracing the whole navigable portion of the globe, is supplied to each of H. M. ships.

(II.) Chart of Line of Equal Magnetic Dip.—This chart shows that the arrangement of the isochinal line is somewhat analogus to that of the geographical equator and parallels of latitude. Hence the line of no dip is called the Magnetic Equator, and the isochinal lines mark what is called the Magnetic Latitude, the Magnetic Poles being the points where the dip is 90°. It must however be borne in mind that the magnetic equator does not coincide with the geographical, and that the isochinal lines are only generally parallel to the magnetic equator. The following relation is approximately true:

#### Tan dip=2 tan mag. lat.

The great use of this chart is to be found in the light which it throws on the changes which the deviations of a ship's compasses undergo on a change of geographical position, chiefly those arising from induction: thus enabling a navigator to anticipate such changes. The magnetism induced in the soft iron by the vertical force of the earth is proportional to that force, and produces a deviation which varies, in different geographical positions, as the tangent of the dip. The value of this tangent is given, in the margin, for each isoclinal line on the chart. The deviation arising from the magnetism induced in the soft iron by the horizontal force of the earth is the same in all parts of the globe.

(III ) Chart of Lines of Equal Horizontal Force. - In some charts the curves of intensity are given showing the distribution of the total force, and the isodynamic curves, in these, will be arranged round four foci of maximum intensity, two in each hemisphere. At these centres the force is between two or three times the amount of that at the magnetic equator, where it is least. But the part of the force, as regard its intensity, which is of special importance to the navigator is the norizontal component; and it is this therefore, and not the total force, which is embodied in the Admiralty Chart. In studying this chart, it must be borne in mind that the relative positions of maxima and minima will be inverted from what they are when the total force At the magnetic equator the vertical component vanishes, and so the horizontal component is identical with the whole of the total force; as we approach the magnetic poles, the vertical component increases while the horizontal component decreases, and the relative value of the latter becomes very small. intensity charts which exhibit the horizontal component only, the maximum will be found near the magnetic equator, and it will diminish as we go towards the poles; though the contrary of this is true when the total force is taken into account. This chart is most important in connection with the effects of the permanent magnetism of the hard from of a ship. This is a disturbing cause which produces deviation inversely as the directive force of the needle (nearly) is one of the parts of the semicircular deviation, and knowing its amount in a ship in any one part of the globe, this chart enables us to estimate its probable amount in any other locality. The multiplier for converting the permanent semicircular deviation at one place to that at another is the product of the value of the horizontal force at the first place, and of the reciprocal of the horizontal force at the second place. These reciprocals are given in the margin of the chart.

Magnetic Equator, Poles, Latitude -- These terms will be understood by a careful perusal of the articles on Terrestrial Magnetism and Magnetism Charts but there are some ambiguities which cannot be too carefully guarded against. The terms, it must be borne in mind, have strictly reference to the magnetic dip.

- 1. The Magnetic Equator is the locus of the places where the dip is zero, or the aclinal curve to which isocimals are approximately parallels. This curve is not identical with the line of minimum intensity of the total magnetic force which is called the Dynamic Equator, but is very approximate to the line of maximum intensity of the horizontal component. The magnetic equator again must not be confused with the Equatorial Plane, which is a plane, at any particular place perpendicular to the line of force, which line is indicated by the dipping needle, and may be regarded as the magnetic axis. This plane is perpendicular to the surface at every point of the magnetic equator, but its position varies in azimuth with the declination.
- 2 The Magnetic Poles are the places where the dip is 90°, or the magnetic axis vertical. These are conscident with the spots where the horizontal component of intensity vanishes and where the equatorial plane is a tangent to the surface.
- 3. The Magnetic Latitude is generally defined as the distance of a place from the magnetic equator; but this is only approximately correct. All places on the isoelimic line are, strictly speaking, in the same magnetic latitude, and these lines are only in a general sense parallel to the equator. Admitting the definition, and assuming the carth to be a sphere and the magnetic equator to be coincident with

the dynamic equator, we may express approximately the different parts of the magnetic latitude, the horizontal force at the magnetic equator being taken as unit.

Hor, force = cosm mag, lat.; vert. force = 2 sm mag lat.

Total force = 1 + 3 sm<sup>2</sup> mag, lat.

In point of fact the range of the total force is from 1 to about 2.5, and the foci of maximum intensity are not coincident with the magnetic poles.

Magnetic Meridian. - The direction of the decimation needle at any place referred to the geographical meridian. Without great care a difficulty may result from the adoption of this term. The object of its use is simply to define that the direction of the horizontal component of the terrestrial magnetism at any place, indicated by the decimation needle, is referred to the geographical north and south as the initial position. Obscurity is introduced by the initial lines. of reference converging to one point, and the isogonic carves, which mark the changes of the magnetic meridian, converging to a different point. In the regions adjoining a magnetic pole, the magnetic meridian passes through every change of position; and as the initial lines or geographical meridians are nearly parallel for a small area. the variation passes through every value from 0° to 360', reckoning. for simplicity, through the whole circle in the same direction same phenomenon is seen in the neighbourhood of a geographical pole resulting from the relatively opposite cause. Here the geographical meridian or initial line itself passes through every change of position and if the declination needle be moved in a small circle round the geographical pole, it will remain parallel to itself for a small area. and hence the variation will here also assume every different value from 0° to 300°.

# Magnetism of Ships.—See under Compass Deviation. Magnitude of Stars.—See Stars, Magnitude of.

Mantissa (L. "overweight").—The decimal part of a logarithm. In the table of common logarithms, whose base is 10, the characteristics are omitted and the mantissa only given.—See Logarithms.

Map (L. "mappa, "a cloth;" hence Sp. mapa; It. mappamonda, the world spread out like a napkin) - A representation upon a plane of some portion of the surface of a sphere, on which are traced the particulars required, whether they be points or lines. A spherical surface, however, can by no contrivance be either "developed" or "projected" into a plane without undue enlargement or contraction of some of its parts. This is immaterial when only small portions of the sphere are to be delineated, but when large tracts are to be mapped down, the distortion in most cases is considerable and inconvenient. There are, however, different methods of projection. the defects of some being the reverse of those of others, and some systems are specially adapted for certain purposes. The word map is a general term, but it has also a more limited sense. Regarding the earth's surface, the word "map" is commonly confined to delineations in which the land is the principal subject of consideration—the map of the geographer; and it is then distinguished from a "chart," in which the wider is the principal subject of consideration -the map of the hydrographer [See Chart.] The term map includes delineations of the celestral sphere.

Mariner's Compass -- A compass fitted for use or board ship. According to the purposes for which it is specially adapted, it is named the Steering Compass, the A much Compass, the Standard Compass. See under Compass.

Markab.—The name of the bright star a Pegasu.—See Pegasus.

Marks.—The depths of the lead-line, which are "marked" by having a distinguishing piece of leather, cord, or bunting rove through the strands. They are, the 10 fathoms (leather with a round hole), 20 fathoms (piece of cord with two knots), and three intermediate to each of these—the 3 fathom (leather), 5 (white rag), 7 (red rag); the 13 (blue rag), 15 (white rag), 17 (red rag). The marks are distinguished from the deeps. When the lead gives one of these soundings the "leadsman" calls it out as, "By the mark—" See Lead-line.

Mars insmed after the Roman god of war).—The superior planet coming next in position to the earth, and being fourth in the order of distance from the sun. Its actual diameter is a little more than one half that of our globe. The apparent angular diameter of Mart varies from 4" to 18", and it can be distinguished by its red and hery appearance. It is one of the "lunar distance" bodies. Symbol 5.

Masthead Angle. - See under Angle.

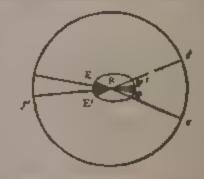

Maxima and Minima. (L. "the greatest and the least"). The max ma values of a varying quantity are those which it has at the moment when it ceases to increase and begins to decrease, the minima values those which it has at the moment when it ceases to decrease and begins to increase. The terms do not refer to the absolute greatest or least value of which the quantity is susceptible. Example: When the barometer rises and then falls, its height at the change is a maximum, even though it should subsequently attain at the change is a minimum, even though it should subsequently fall to a greater extent.

Maximum (L. "the greatest").—A value which a varying quantity has at the moment when it ceases to increase and begins to decrease.—See Maxima and Minima.

Mean Level of the Sea.—The middle plane between the levels of high and low water. ~See Level of the Sea.

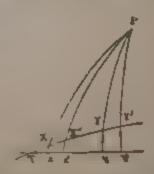

Mean Sun A fictitious sun which is conceived to move

uniformly in the equinoctial with the mean velocity the real sun has in the ecliptic. The mean sun furnishes us with a uniform measure of time, and the need for the conception arises from apparent solar time being variable. The apparent solar day is variable from two causes—(1) the variable motion of the

ann in the ecliptic, and (2) the ecliptic not being perpendicular to the axis of the earth's rotation. (1) The earth moves in an elliptic orbit (EEFF) round the sun in one of the foci (S), and, by a law of such motion, sweeps out equal areas (as ESE' and FSF'), and therefore describes unequal angles as (ESE' and FSF') in equal times. Hence the sun appears to move sometimes faster and sometimes slower in the ecliptic (describing, for example, ee' and ff' unequal arcs in equal

times. He, in fact, at one time describes an arc of 57 in a day, and at another time as much as 61'. This will cause the apparent solar day to vary in length. (2) But, again, even supposing the motion of the sun in the scliptic to be uniform, this circle is not perpendicular to the axis of the earth's rotation, and, consequently, equal arcs will not subtend equal angles at the

pole of the housens, such angles measuring equal intervals of time. Let XX' and YY' be equal arcs of the ecliptic, the former near the equinoctial point (T), where the ecliptic is inclined to the equinoctial at an angle of about 23° 27, and the latter in the vicinity of the soletitial point, where the two circles are parallel. Draw the hour-circles I'Xx, I'Xx and I'Yy, I'Yy; then it is evident that the angles at the pole xi'x and yPy', or the corresponding arcs of the equinoctial, are not equal

The connection between the true and mean sun is established and follows. Imagine a star to move along the ecliptic with the mean or average motion of the true sun, the two starting together from the extremity of the major axis of the ellipse. Let our fictitious sun so move in its uniform course along the equinoctial that it and the star may cross the first point of Aries together, at which time the true sun will be a little whead. The true and the mean sun will never be together, but four times a year they will be on the same declination circle; the equation of time, which is the difference between the right ascensions of the two suns, will therefore vanish four times a year.

Mean Time.—Time in which the unit of duration is a mean solar day, the length of which is the average of the days throughout the year. Its lapse is astronomically defined by the motion of the ficturous point called the Mean Sun.—See Time.

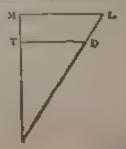

Mercator's Chart.—A chart constructed on an artificial projection called after its partial inventor Gerard Kanffman, the Latin equivalent of whose name is Mercator ("inerchant"). He was born in East Flanders in 1512, and first published his chart in 1556. In this chart all the meridians are parallel right lines, and the degrees

of longitude are all equal: the parallels of latitude are at right angles to the meridians, and the degrees of latitude increase in length from the equator to the pole in the same proportion as the degrees of longitude decrease on the globe. It will be seen at once, from the manner in which the meridians are projected, that a spiral on the globe which cuts them at a constant angle (the rhumb) will be projected on the plane into a straight line. It is this property which renders the Mercator projection so invaluable to the navigator.

Though Kauffman made his degrees of latitude increase with their distance from the equator he does not appear to have known the law which regulates them—That the increments of the meridian (the small portions by which it is successively increased) vary as the secants of the latitude. This characteristic of the true chart was discovered by Edward Wright, an Englishman, about 1590, and was communicated by him to Mr. Blun lerville, who published it in 1594. Wright gives it in his "The correction of certain Errors in Navigation," 1599 The perfection of the chart depends upon the degree of accuracy to which the Table of Meridi mal Parts is constructed. This has advanced with modern mathematical science, and more extended geodetic measurements.—See Meridional Parts.

Mercator Sailing -A method which completely solves the problems of spherical sailing, and which is characterised by the use

of the l'abl of Meridional Parts, and the chart constructed by means of it called Meridion's Chart. With the assistance of this table, the rules of plane trigonometry suffice for the solution of all the problems. In the triangle CTD, let C be the course, CD the distance, CT the true ifference of latitude, TD the departure; then,

corresponding to CT, the Table of Meridional Parts gives CM the ineridional difference of latitude, and, completing the right-angled triangle CML, ML will be the difference of longitude. In addition, then, to the three canons of plane sailing which can be deduced from the triangle CTD, the triangle CML gives the characteristic canon of Mercator sailing (since ML=CM, tan C).

Diff. long. = mer. diff. lat. x tan course.

Mercury (called after the Roman god of merchandise).—One of the inferior planets that which revolves nearest to the sun, from which it never attains a greater angular distance than about 29°. It is seldom visible to the naked eye, and then only at sunrise and sunset. Its actual diameter is about two-fifths that of the earth; the apparent angular diameter varies from 5" to 12". Symbol §.

Moridians (L. meridies from medius dies, "mid day"). If we consider the earth a sphere, the meridians are great circles of the earth passing through the poles. They are so called because they mark all places which have noon at the same instant. They are secondaries to the equator, and on them latitudes are reckoned north and south from that primitive. They mark out all places which the same longitude, and are hence called "Circles of longitude." Is is usual to consider each semicircle joining the two poles of the earth. The above definition is only correct if the earth is as a meridian. regarded as a sphere. If we take into account that the earth is an oblate spheroid, it must be replaced by the following. Meridians are curves which are the sections of the earth's surface by phones passing through the two poles. These curves are ellipses, whose major and minor axes are respectively the equatorial and polar diameters of the earth.

Meridian (Terrestrial) of an Observer.—The section of the earth by a plane passing through the poles and the station of the observer. If the earth is regarded as a sphere, this section is a great circle; if its spheroidal figure is taken into account, the section is an ellipse.

Meridian (Celestial) of an Observer.—The great circle of the celestral concave in which the plane of the terrestrial meridian indefinitely extended intersects it. It is the circle passing through the elevated pole of the heavens and the zenith of the observer. By the rotation of the earth the observer's meridian, like the horizon, aweeps daily from west to east across the heavenly bodies projected on the celestial concave. If the earth be conceived to be at rest, the meridian is a fixed circle, and all the heavenly bodies are carried across at in their diurnal courses from east to west. It thus, as its name expresses, serves as a circle of reference for the diurnal motions of the heavenly bodies; great circles of the heavens co-axial with it, and passing through these several bodies, are called their "hourcircles." We must carefully bear in mind the distinction in the phrases-"the celestial meridian of an observer on the earth," "the hour-circle of a heavenly body." With reference, however, to the diurnal motion, the meridian is considered the initial position of the hour-circles, which thus mark out at the pole "hour-angles," reckoning westward. The celestial meridian intersects the horizon in the north and south points, and its poles are the east and west points. The celestral meridian is often samply spoken of as " The Meruduen "

Meridian Line. —A meridian line is the line in which the plane of the meridian of any station intersects the plane of the sensible horizon; it meets the celestral horizon in the north and south points.

Moridian Altitude — The meridian altitude of a heavenly body is its altitude when on the meridian of the observer's station. It is in general the greatest altitude which the body attains in its durinal revolution, or, when the body culminates twice, the greatest and the least altitude. The meridian altitude is easily observed at sea with the sextant, when the body comes to the meridian its image appearing to remain stationary for a short time and then to "dip."

Meridian Distance.—The difference in time between the meridians of two places. This is an application of the term "distance" which is confusing and unnecessary. We recommend the substitution of Chrimometric Infference as being much more appropriate.—See Longitude; Difference of, in Time.

Meridian Zenith Distance.—The meridian zenith distance of a heavenly body is its zenith distance when on the meridian of the observer's station. It is the complement of the meridian altitude

Meridional Difference of Latitude. The quantity which bears the same ratio to the difference of latitude that the difference of longitude bears to the departure. It is the projection of the difference of latitude on the Mercator's chart, and takes its name from the "Meridional Parts," by the use of a table of which it is found.

Moridional Parts.—At the equator a degree of longitude is equal to a degree of latitude, but, as we approach the poles, while supposing the earth to be a perfect sphere) the degrees of latitude remain the same, the degrees of longitude become less and less. In the chart on Mercator a projection the degrees of longitude are made everywhere of the same length, and therefore, to preserve the proportion that exists at different parts of the earth's surface

between the degrees of latitude and the degrees of longitude, the former must be increased from their natural lengths more and more as we recede from the equator. The lengths of small portions of the meridian thus increased, expressed in minutes of the equator, are called "meridional parts"; and the Meridional Parts for any intitude is the line, expressed in minutes (of the equator), into which the latitude is thus expanded. The meridional parts computed for every minute of latitude from 0° to 90°, form the Table of Meridional Parts, which is chiefly used for finding that meridional difference of latitude in solving problems in Mercator's sailing, and for constructing charts on the Mercator's projection. The value of the meridional parts may be obtained appproximately from the formula

Mer. parts for  $l' = \sec 0 + \sec 1' + \sec 2' + \dots$  sec (l' - 1); and it was from a similar expression that the first table of meridional parts was computed by Edward Wright in 1594. The integral calculus now furnishes the means of finding the meridional parts correctly, the formula obtained being -

Mer. parts for 
$$l^{\circ} = \frac{180 \times 60}{\pi} \log_r \tan (45^{\circ} + \frac{l^{\circ}}{2})$$
.

Meridional Projection of the Sphere —A projection of the aphere, whether orthographic, stereographic, or central, in which the primitive or plane of projection coincides with, or is parallel to, the meridian.

Meteorology (14k. τὰ μετέωρα, "things in the air"; λόγοι, "a treatise").—The science which treats of the atmosphere and its phenomena; for the navigator it is the science of the winds and the weather. The various subjects of which it takes cognishance will be indicated by the mention of some of the principal institutions used.

The Barometer (Gk. βάροι, "weight") measures the pressure; the

Thermometer (Gk. τὸ θερμὸν, "heat"), the temperature; and the Hygrometer (Gk. τὸ ὑγρὸν, "mousture,") the mousture of the atmosphere; the Anemometer (Gk. ἀνεμος, "wind") indicates the atrength and velocity of the wind; and the Pluviameter (L. pluvia, "rain") gauges the rain.

Mètre (Fr., from Gk. µέτρον, "a measure").—The French standard measure of length, being the ten-millionth part of the quadrant of the meridian. The other measures of length are referred to this, the whole system being decimal; Latin prefixes are used to indicate division, Greek prefixes multiplication. Thus a decimative (decem, "ten"), is the tenth of a metre; a contimetre (centum, "a hundred"), the hundredth part of a metre; a millimetre (mille, "a thousand"), the thousandth part of a metre. Again, a decamatre (δέκα, "ten") is ten metres; a hectomètre (έκατον, "a hundred") is one hundred metres; a kilometre (χίλιοι, "a thousand"), one thousand mêtres; a myriametre (μιριάς, "ten thousand"), ten thousand mêtres. A mêtre is equal to 39'37079 English metres; and from this all the other French measures may be obtained by shifting the decimal point.

Middle Latitude.—With reference to two places situated in the same hemisphere, the middle latitude is the latitude of the parallel passing midway between them; its value is therefore half the sum of the latitudes of the two places. When the places are situated in different hemispheres, the simple "middle latitude" is replaced by the two "half latitudes" of each of the places.

Middle-Latitude Sailing. -An approximate method of solving certain cases of spherical earling, founded on the consideration that the are of the parallel of middle latitude of two places intercepted between their meridians is nearly equal to the departure. If the

ship is conceived to sail along this middle parallel, we may apply the principle of parallel sailing to the cases in point. In parallel sailing the departure (or distance) and difference of longitude are connected by the relation,-

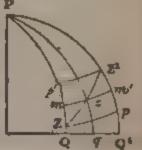

Dep. = diff. long. x coalat.

When the ship's course lies obliquely across the meridian, making good a difference of latitude, a modification of this formula gives the formula for middle-latitude sailing, -

Dep. (nearly) = diff. long. x cos mid. lat.; or, in logarithms,

log dep. = log. diff. long. + L cos mid. lat. - 10. In the proof of the fundamental principle of middle-latitude sailing two cases must be considered separately—(1) When the place from and the place in are on the same side of the equator, and (2) When they are on different sides of it.

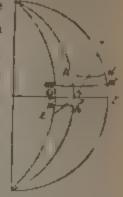

1. Let the two places Z and Z' be in the same hemisphere, Z being nearer to the equator than Z'. Draw the p parallels Zp and Z'p through Z and Z', and the middle parallel m 2 m'. Then the departure between Z and Z' is less than Zp and greater than p' Z'; and, in the cases where middle latitude sailing is applicable, the defect on one side is not very different to the excess on the

other and they are assumed to be equal. Hence mam' may be taken sa an approximation for the departure, especially for short distances; and as far as the departure is concerned, and consequently the difference of longitude, the ship may be supposed to have sailed siong the parallel mm'. Thus the case is reduced to parallel earling.

2. When the two places Z and Z' are in different hemsepheres,

their latitudes being of different mines, the mildle latitude fails to give an arc of a parallel which is an approximation to the departure. Practically, however, when the latitudes are of contrary names, no sensible error can arise from taking the departure itself made good from day to day as the difference of longitude. For greater distances we may consider separately the departure made good on each side of the equator, and thence find the difference of longitude, though the

plan fails for the converse problem. Thus, let the rhumb line between Z and Z' cut the equator in  $l_o$ , and let nh be the arc of the parallel of the half latitude of Z intercepted between the meridians of Z and  $l_o$ , and n'h' the arc of the parallel of the half latitude of Z' intercepted between the meridians of Z and  $l_o$ . Then by previous case,

nh is an approximation to the departure in sailing from Z to i, and hin' do. do. 4 to Z : nh + h'n'do. do. Z to Z Hence it will be seen that we can thus deduce the difference of longitude Qlo + lo Q; but conversely we cannot find the approxunate departure nh + h'n' from the difference of longitude QQ'. since the position of the point le is not known. For ordinary purposes, when the two latitudes are numerically very nearly equal, or very unequal, correct enough results will be obtained by employing as the middle latitude half the greater latitude. In intermediate

cases we may combine the two middle latitudes, giving the greater weight to that which corresponds to the greater latitude. The fundamental problems of navigation may be completely (though only

approximately) solved by the middle-latitude method, just as they are in parallel sailing by inspection of the traverse tables. —See Sailings.

Mile (L. miliare, the mille passus "thousand paces" of the Romans). The Roman pace was 5 Roman feet, each to about 11 62 English inches. The ancient Roman mile was, therefore, equal to 4842 English feet, or 1614 yards.

Mile, English Statute. - The common and authorized mile used by the English for itmerary and legal purposes. It consists of about 1000 ancient Roman paces. Its length is mendentally laid down, in a Statute (forbidding persons to build within three " miles " of London) of the 35th year of Queen Elizabeth, as being 8 furlongs (a contraction for forty-"longs") of 40 perches of 164 feet each. This is more easily remembered as being 8 furlongs of 220 yards each; and it is equal to 80 land-surveying chains of 22 yards each

l statute inile = 1760 yarde = 5280 feet.

I English statute mile 1.61 French kilomètre.

Mile, Geographical or Nautical -The Geographical Mile was formerly defined as "the length of a minute of the earth's circumference", and it is hence also called a "Minute". It is that used in navigation, and hence called the Nautical Mile, and whom used as a measure of speed a "knot," from the manner by which the rate of a slop is obtained and estimated in miles per hour.

The above definition of the mile used at sea, "the length of a minute of the earth's encounference," is we yimadequate; but it is purposely here given as a general and preminanty one to explain the different values assigned to the nautical mile in books on navigation, which are very perplexing to the mariner. It was sufficient before

the spheroidal figure of the earth was taken into account, and when the assumption was that the earth's circumference was a great circle, the measurement of which had not been accurately determined.

Sir Jonas Moore ["A New Systeme of the Mathematicks," 1681] takes the length of "a minute of a degree of a great circle of this terraqueous globe" to be 6000 English feet. The general custom before his time was to use the value 5000 feet, but experience had proved that the distance run, obtained by a corresponding "knot," "did not answer to the parts of a degree," and the half-minute glass had been shortened in consequence by about 5 seconds of time. John Robertson ["The Elements of Navigation," 1786] deduces the length of a "sea" or "nautical mile" to be 6120 feet, as "by Mr. Richard Norwood's experiment it appears that a degree of a great circle on the earth contains 367,200 English feet." John Riddle calculates the nautical mile to be nearly 6079 feet, on the assumption that the earth is "nearly equal to a sphere of 7916 English miles in diameter."

The section of the earth which approaches most nearly to a great circle is the equator, though the greatest and least diameters of even the equator differ by about 9768 feet. Taking Bessel's value of the equatorial diameter of the earth, viz. 41,847,192 feet, the length of a minute of this great circle would be 6086 feet, which nearly corresponds to the length of the nautical mile (viz. 6086 7) used by Nathamel Bowditch for finding the length of the knot (see "The New American Practical Navigator."]

The nautical mile should always be associated with the length of a minute of a degree of latitude. The meridian, however, being an ellipse, this varies much in different latitudes, at each spot depending upon the radius of curvature. At the equator the length of the minute of latitude is 6045-93 feet; in latitude 45° it is 6076 82 feet;

at the pole it is 6107 98 feet. If we define the nautical mile as "the mean length of a minute of latitude," its value would thus be about 6077 feet. James Inman uses 6075 5 as the value of "a mean nautical mile." Henry Raper, for the purpose of computing a Table of Depression, finds "the length of the average nautical intle 6082 feet (nearly)." To obtain this "average length" he assumes an arbitrary latitude, viz. 40°, marking the region most frequented by shipping; and, as the curvature of the earth is different on the prime vertical and on the meridian, he employs the circle of curvature crossing the meridian at 45° of azimuth. In estimating, however, the length of the "knot," he uses the approximate value 6080 feet. II. W. Jeans follows this practice. The number 6080 has been generally adopted as a convenient value for the knot, and is in general sufficiently near for practical purposes. It is strictly the value of a minute of latitude on the parallel of 48°.

The nautical mile in use is, in fact, different according to the purpose for which it is employed. There are three distinct applications of it in cognate branches of naval science, which should not be confused, and for which it is desirable we should have separate definitions.

- The Hydrographer's Mile is "the length of a minute of latitude on the parallel under treatment."
- 2. The Navigator's Mile is "the average length of a minute of the meridian."
- 3. The Ship-builder's Mile is "the measured mile of a fixed number of feet."
- I Hydro prophers use every different value of the geographical mile, and construct their local charts on the basis that the mile is a

mile of latitude on the parallel under treatment. But, as a mile should be understood as a fixed quantity, there is an anomaly in so using the term unless there is associated with it a definite measure, such as a mile of 6080, or 6085, or 6086 feet, as the case may be. Our surveyors, therefore, invariably make a notation of this value, which is obtained from Geodetical Tables.

- as we have seen, has varied at different periods with advancing knowledge of the earth's form and magnitude. It is that which technically termed the "knot" is used to estimate the ship's run at sea. In navigating a ship in equatorial and polar regions we should, if rigidly accurate, have to change the length of the knot with the latitude; but for the ordinary purposes of navigation the average nautical mile may be used in high and low latitudes without fear of error as affecting the ship's run. The mean value of a mile of latitude, viz. that on the parallel of 45°, is 6077 feet; there seems to be no reason why this value should be not universally adopted, except that the number 6080 commonly used is easily remembered, and the difference resulting from the use of the two would not amount to one mile in 2000.
- 3 Ship builders, since the introduction of steamers, have adopted a nautical mile of fixed value in feet to test a ship's speed. This is called a "measured mile" A uniform measured mile has not, however, been defined by authority. The Admiralty itself uses two different lengths, the measured mile on the Thames being 6085, and that at Plymouth 6083 feet. This difference, as given on the charts, may possibly be accidental, or perhaps it is a remnant of the times when rival constructors at Woolwich and Devenport were independent, and adopted a value for their measured mile from the

approximate geographical mile of the latitude of their dockyard. Should a uniform "measured mile" ever be introduced, it would be desirable to assimilate it with that which is afterwards used in logging the rate of a ship at sea.

Miles, Geographical and Statute.—The length of the average geographical mile being 6076.82 and that of the English statute mile 5280 feet; we have—

- I Geographical mile = 1.151 statute mile,
- 1 Statute mile = '868 geographical mile.

The convergent fractions which express the ratio of the geographical mile to the statute mile are—}, \( \xi\_1, \xi\_2, \xi\_3, \xi\_4, \xi\_4 \xi\_4 \xi\_4 \xi\_5, \xi\_5 \xi\_6 
Mile, Metrical.—The French "kilometre" (1000 mètres) is sometimes so called. It is the length of one-hundredth part of a quadrant of the meridian. A kilometre = 39370.79 English inches = 3281 feet = 1093 yards = '62 statute mile. This mile is the same as the Mijle of the Netherlands and the Stadion of Greece,—See Mètre.

Milky Way (L. Via Lactea; Gk. & yakatlas xóxkos "The Galaxy").—A luminous zone (varying in breadth from 5° to 22°) visible on a clear night, which may be referred to a great circle of the sphere named by Sir John Herschel The Galactic Circle—This circle is inclined at an angle of about 63° to the equinoctial, which it cuts at points whose right ascensions are 0h 47m and 12h 47m. The phenomenon is the result of the light of innumerable stars of every magnitude, from such as are visible to the naked eye down to the smallest point of light perceptible with the best telescope. The appearance of these as a belt is explained by the hypothesis of Sir William Herschel that the grouping of the stars of our firmament in

in the form of a stratum, of which the thickness is small in comparison with its length and breadth, and that the solar system is situated somewhere about the middle of its thickness. A visual ray traversing from the edge of such a lamina would pass through more stars than one perpendicular to the lamins.

The principal use of the Milky Way to the seaman lies in the aid it affords him in recognizing the stars, especially on a bright night, when it is more difficult than usual to single out the body required for an observation. The most convenient way to study it, in each hemisphere, is to take for our starting point the spot where it approaches nearest to the pole; and it so happens that in both cases this is marked by a conspicuous easily detected constellation.

Northern Hemisphere.—Cassiopeia's Chair is situated near the spot where the Galaxy passes closest to the North Pole. From this point, if we follow it in the direction of the diurnal motion of the beavens, it passes through Cophens, sending off a spur towards the Pole : in Cygnus it divides, unites again, and then separates into two branches. The branch nearest to the Pole, after passing to the south of Lyra, terminates near a and B Ophinchi. The other branch passes through Aquida, then widens out till it comes to Sagittarius, and at 7 Sagittarli it suddenly collects into a vivid oval about 60° in length and 4° in breadth, the product of upwards of 100,000 stars. A parallel patch here appears in Scorpio. If we now return to Cassioners and advance in a direction contrary to the diurnal motion of the heavens, the Way passes through Perseus, where it sends offan offshoot to a considerable distance; then it passes near Auriga, between Tourns and Gemini, and between Orion and Canis Minor; after bending round Sirus and sending off a branch near a Puppis, in Argort opens out into a wide fan like expanse nearly W in lacable. which terminates absuptly, and a wide gap succeeds.

Southern Hemisphere.—The Southern Cross is situated near the spot where the Galaxy passes closest to the South Pole. Here also is one of its most remarkable black patches, caused by an entire absence of stars. This space is of an irregular pear-shaped form about 8° in length and 5° in breadth; such a striking object is it that the early navigators called it the Coal Sack. From this point, if we follow the Way in the direction of the Diurnal motion of the heavens we soon come to Aryo, to which locality we have traced it from Cassiopeia. If we proceed from the Coal Sack in a direction contrary to the diurnal motion, the Way passes Centaurus, then widens out and subdivides into several irregular branches and patches which permeate Scorpio. To this locality we have also traced it from Cassiopeia.

Millimètre (L. mille, "a thousand"; Fr. mêtre) -A French measure of length, being the thousandth part of the metre, and equal to '039 English meh.

Minimum (L. "the least") —A value which a varying quantity has at the moment when it ceases to decrease and begins to increase. —See Maxima and Minima.

Minute. - A mutical mile is sometimes so called as being the mean length of a minute of latitude. A minute of latitude is often conversely called "a mile," which, however, is not quite correct, as, while the mile is of invariable length, the minute of latitude varies on different parts of the meridian. Great care should be taken not to call a minute of longitude "a mile," as the minute of longitude is of very different lengths in different latitudes.

Monsoons (Arabic and Malay, mosseem, "a year"). —A term originally used for the periodic winds of the Indian Ocean, but now

extended to include all currents of the atmosphere caused in a simular manner. They are for the most part trade-winds deflected at stated seasons of the year, and are found in regions where the sun in one part of his course is vertical over large tracts of arid land, and at another part of his course over large tracts of sea. Thus the African monsoons of the Atlantic, the monsoons of the Gulf of Mexico, and the Mexican monsoons of the Pacific, are caused by the trade-winds which are turned or deflected to restore the equilibrium which the overheated plains of Africa, Utah, Texas, and New Mexico have disturbed: and similarly in the Indian Ocean, where the monsoon phenomena are developed on the grandest scale, their range being the whole expanse of northern water that lies between Africa and the Philippine Islands. The heat of summer creates a disturbance in the atmosphere over the interior plains of Asia, which is more than sufficient to neutralize the forces which would cause a regular north-sast trade-wind. The north-east trade-wind is arrested and turned back, and the result is a south-west monsoon, which continues for six months from April to October. During the other six months, from October to April, these causes act in concert with the tradewind, and what in other seas would be called the north-east trade. is in this case called the north-east monsoon. The south west monsoons commence at the north, and "back down," or work their way towards the south; thus they set in six or eight weeks earlier at the tropic of Cancer than at the equator. The change from the one to the other is accompanied by violent rains, with storms of thunder and lightning. It is this south-west boisterous wind that is generally spoken of as The Monsoon,

Moon (Sax. mona: analogues—Lat. luna; Gk. continued but which words are sometimes found in derivatives e.g. because

eclenography).—The secondary planet or satellite of the earth, revolving in an orbit round the earth, being at the same time carried with it, and participating in its motion round the sun; the actual orbit, therefore, which the moon describes in space is very complicated. The moon's distance from the earth is about 60 times the earth's radius, and her actual dismeter 2153 miles. But it is with the apparent orbit of the moon and resulting phenomena, her apparent size, the effect of her proximity to an observer, and with her influence, that the practical navigator is chiefly concerned.

The apparent orbit is, speaking generally, a great circle of the heavens, like that which the sun appears to describe round the earth. In this circle the moon seems to advance rapidly among the stars with a movement contrary to the diurnal revolution of the heavens. Progressing sometimes quicker, sometimes slower, she completes the tour of the heavens in an average period of 27d 7h 43m 11 5s. This motion among the stars is the foundation of several important methods for determining the longitude, "lunar distances," "occultations," and "moon-culminating stars."

The apparent diameter of the moon varies with her distance from the earth, the greatest value being 33' 31', and the least 29' 22'. The semi-diameter is one of the corrections to be applied to observations. The propinquity of the moon to the earth also causes her place as seen from different places on the earth's surface, to differ from her place as seen from the centre; hence the parallax is a considerable correction in reducing apparent elements. The mean value of the horizontal parallax is 57' 1'8'.

The lunar influence is most conspicuous in the phenomena of the tides, in the calculations of which the lunar elements occupy the most

prominent place. The only other point to be alluded to is the meteorological fact of the tendency to disappearance of clouds under the full moon.

Moon, Age of.—The elapsed portion of a lunation which is the period from new moon to new moon, the average length of a lunation being 294 days. The moon's age is given in the "Nautical Almanac," p. iv., of the month, for every mean noon at Greenwich; and hence it may be deduced for any other Greenwich date. For many purposes it is convenient to be able mentally to calculate, without reference to books, what will be the approximate age of the moon on some future day. The following method will be found useful.

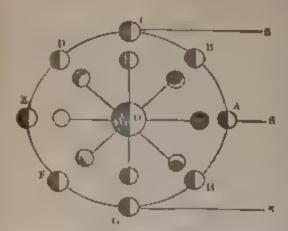

First—Obtain the Epact for the Year, or age of the moon on the preceding 31st December. This is given in the "Nautical Almanac," and is very nearly 11 days more each year than in the preceding, it may therefore be always practically found by adding 11 to the epact of last year and rejecting 30, if necessary.

Secondly—Obtain the Epact for the Month, or age of the moon at the end of the previous month, supposing the moon to change on lat January. In January a lunation is taken as equal to 29 days, in February to 30 days; for March, May, and July, it is taken at 29 days; and for April and June, at 30 days; as a lunation is not accurately 29} days, it is found better to distribute the error equally among the succeeding months. The figures thus obtained can be remembered without difficulty after having seen them written in three lines beneath the months, forming a pyramid, where it will be observed that the only odd figures fall below the cyphers.—

Jan. (1) Feb. (2) March (3)
O 2 O
April (4) May (5) June (6) July (7)
2 2 4
Aug. (8) Sep. (9) Oct (10) Nov. (11) Dec. (12)
7 8 9 10

Thirdly.—To the Epact for the Year add the Epact for the Month, and then the Day of the Month, and reject 30, if necessary. Examples.—Age of moon on June 12, 1882 = 11 + 4 + 12 = 27 days; this therefore was not a moonlight night. Age of moon on August 17, 1883 = (11 + 11) + 6 + 17 - 30 = 15; this was therefore a moonlight night.

Moon's Phases (Gk. odors, "an appearance").—The moon is an opaque body, and, being illuminated on one side by the sun, reflects from its surface in all directions a portion of the light so received, and thus, as seen from the earth, presents through the course of a lunar month different aspects; these are called her phases. Let O be the earth, A, B, C, etc., various positions of the moon in her orbit, and S the sun, whose distance is so vast that rays of light to all parts of the moon's orbit are very nearly parallel. Then, wherever the moon is in her orbit, that hemisphere towards the sun will be bright, and the opposite hemisphere dark; but the face turned towards the earth will in general be partially illuminated, the remainder of the disc being only faintly visible, if visible at all. In the position A, when in conjunction with the sun, the dark part of the moon is entirely turned towards the earth at O. and the bright side from it. Here the moon is not seen from the earth; it is now said to change, and is called the new moon. When she comes to C, half the bright and half the dark hemisphere are presented to O, and the same is the case in the opposite situation (i); these are respectively called the first and third quarters of the moon. Again, when at E, in opposition to the sun,

the whole of the bright hemisphere is towards O and the whole of the dark side from O, and it is now full moon. In the position B the portion of the bright face presented to O will be less than half the disc, this visible portion increasing from A to C. Here the appearance of the moon is described as

erescent (L. crescens, "mereasing"). In the corresponding position H, where the moon is waning, her form is the same, though differently placed. When in the positions D and F, the portion of the bright face presented to O will be more than half the disc; and here the appearance is describe as gibbous (L. gibbus, "a swelling.")

Moon's Horizontal Semi-diameter, Augmentation of.—When a colestial body, whose distance bears a definite ratio to the radius of the earth, is in the zenith, it is nearer to the spectator by the earth's semidiameter than when it is in the horizon; hence its apparent magnitude is largest when in the zenith. This increase of apparent diameter due to increase of altitude is sensible in the case of the moon only, her distance not bearing too great a ratio to the earth's radius. The moon's semidiameter put down in the "Nautical Almanac" is computed on the supposition that the spectator is at the centre of the earth, and is the same as it would appear when in the horizon of any spectator on the surface. When she is between the horizon and zenith, her apparent semidiameter is somewhat greater than that which is taken out of the "Nautical Almanac." The correction to be added is given in a table as "Augmentation of the

Moon's Horzontal Semidiameter"; its greatest value being 18".

This correction is calculated by the formula:—

Aug. = 2 R. cosec 
$$(z' - p) \sin \frac{p}{2} \cos (z' - \frac{p}{2})$$

where R = moon's horizontal semidiameter,

z' = moon's apparent zenith distance,

p = moon's parallax in altitude,

= hor. par. × cos (app. alt.).

When the sun and moon are near the horizon their magnitudes appear to be much greater than when they are at a considerable altitude; and so all constellations of the stars, as the Great Bear, appear to occupy a much larger space when in the vicinity of the horizon than when nearest the zenith. This, however, is an optical illusion, as measures taken with instruments prove.

Moon's Semidiameter, Contraction of.—When the moon is near the horizon her disc assumes an elliptical form, in consequence of the unequal effect of refraction. If, therefore, a distance be observed between another body and the moon's himb when her altitude is low, before applying her semidiameter its value must be corrected. Let  $\theta$  be the angle which the line joining the centre of the other body and that of the moon makes with the horizon, r the moon's radius in the direction of this line, a her radius in a horizontal direction, b her radius in a vertical direction. Let A be the altitude of the moon's centre and b the difference of refraction for altitudes (A + b) and A, which can be taken from the Table of Refractions, Then—

Correction  $(a - r) = \delta \sin^2 \theta$ .

Moon's Horizontal Semidlameter and Horizontal Parallax.—The values of the semidlameter and parallar when the moon's centre is in the horizon. See Horizontal.

Moon-Culminating Stars.—Stars which, being moon's parallel of declination, and not differing much right ascension, are suitable to be observed with the determine differences of meridian. This is effected by condifferences of the observed right ascensions of such a moon's bright limb at any two meridians, such differences reason of the moon's rapid proper motion. Knowing increase in right ascension, we may thus easily find the longitude.

Motion, Proper.—Strictly speaking, the proper heavenly body would be that due to its own movement as different its apparent change of place resulting from a chaposition of the spectator. The term, however, is technical such total motion of the body as is independent of the earth's rotation on her axis. Thus, the proper motion of his motion in the ecliptic as distinguished from his adjurnal parallel; though the former is the result of the earth; in her orbit, just as the latter is of her rotation on her axis.

Nadir (Arabic; compare Ger. nieder, Eng. and inferior pole of the celestial horizon. It is the point of westwardly under a spectator's feet, the vertex of the hemisphere. The nadir is diametrically opposite to the Term new but seldom used.—See Zenith and Nadir.

Napier's Diagram and Curve.—A method of and value for extending and utilizing the results of a limital observations for representing the deviation of a ship's of complete Table of Deviations may be drawn up by its aid furnishes the means of deducing by inspection the magnetic or responding to a given compass course, or the com-

corresponding to a given magnetic course. The Diagram is engraved, and copies are supplied to each of H.M. ships; a full description of diagram and curve with their uses will be found in the "Admiralty Manual for the Deviations of the Compass."

Natural Projections.—Perspective delineations of a surface on a given plane. They are formed by drawing from the eye straight lines, indicating the visual rays, through every point of the surface to meet the plane. The original and the representation produce the same effect on the organ of vision. Examples—the orthographic, stereographic, and central projections of the sphere. Distinguished from Artificial Projections.—See Projections.

Nautical (L. nauticus, Gk. vauticus; L. nauta, Gk. vautus, "a navigator"; L. nauts Gk. vaut, "ship").—Belonging to ships; pertaining to a seaman's business. The term is applied in a general comprehensive sense. Thus nautical science includes the two branches of navigation and seamanship.

"Nautical Aimanae" (Arabic; al, the article; manah, "to reckon").—A work published by the Admiralty for the special use of seamen. It was projected by Dr. Maakelyne, Astronomer Royal, and first published by the Board of Longitude for the year 1767; in its present approved form it appeared in 1834. The "Nautical Almanae" is brought out four years in advance, and contains all the elements required (in addition to those observed) in celo-navigation, for the practice of which it is an essential appliance. Besides the information necessary for a navigator, the "Nautical Almanae" contains the register and prediction of the phenomena which are the subjects of astronomical science generally; in fact, its full title is "The Nautical Almanae and Astronomical Ephemeris."

The "American Nautical Almanac" is substantially the that portion of our own intended for the practical use of nat. It was first published for the year 1855. By Act of Cong. meridian of the observatory at Washington was decreed. American meridian for astronomical purposes, but the meridian for all nautical purposes. This latter subdivision of "The American Ephemericand Nautical Almand to the publication of two separate volumes. The first all the information necessary for navigation, and is publish years in advance.

The title of the French Nautical Almanac is "Connaise Temps."

The German Nautical Almanac "Berliner Astronomers for the given to the Ephemerides of the minor planets.

Nautical Astronomy.—Astronomy in its applied navigation. It has been usual to distinguish by this term that of the science of navigation which calls in the aid of astronomical activities beavenly bodies. The objection to its being thus applied to implies a branch of the science of astronomy rather than a but the science of navigation; "astronomical navigation won more correct though a cumbrous phrase. We suggest the of the term cele-navigation for this branch of the science, disting the other as geo-navigation.—See Navigation;

Nautical Day.—See under Day.

Navigation (L. navigo, "to sail," from Gk, ναθι, L. ship"; Gk, άγω, L. ago, "to lead," "drive," "deal with

science which treats of the determination of a ship's place at sea, and which furnishes the knowledge requisite for taking a ship from one place to another. The two fundamental problems of navigation are, therefore, the finding at sea our present position, and the deciding our future course. There are two methods of navigation, which I have distinguished as (1) Geo-navigation, and (2) Celo-navigation.

 In Geo-navigation (Gk. γη, " the earth ") the place of the ship. at sea is determined by referring it to some other spot on the earth's surface, either (1) some known landmark, (2) a determinate bottom, or (3) a previously defined place of the ship. (1) The rudest manner of making a voyage (that used by savage tribes) is by Consting; and this requires only local knowledge, no instruments being necessary. Among civilized nations also, when a ship is in the vicinity of land its position is found upon the same principles. In this case its actual position is often a matter of vital importance; and with a good chart, azumuth compass, and sextant, simultaneous bearings of two or more objects, or the measurement of an angle, give it with facility and precision. (2) When near, though out of sight of land, we may, if we possess the results of good surveys, determine, or help to determine, our position by consulting the depth and nature of the bottom by Soundings (3) When a snip leaves the vicinity of land and stretches across the open sea, we can find its position at any time by referring it to some previous position of the ship. For this purpose we require, besides a chart of appropriate construction, a time-piece to note the interval, the log-line and glass to measure the rate of sailing, while the mariner's compass also directs our future course. The process of thus estimating a ship's place is called Dead Reckoning; it has been practised in Europe since the end of the twelfth century, when the compass was introduced. The compass is, however, recorded to have

been known to the Chinese in very remote ages. It has been customary to apply the term "navigation" in a restricted sense to the method we have described as "geo-navigation"; but it would be very advisable that this term "navigation" should always be used in its generic or general sense.

2. Celo-narigation (L. calum, "heaven," from Gk. molkov, "hollow"). In this method the position of the ship is determined by finding the zenith of the place from observations of the heavenly bodies, and our future course is pointed out by their bearings. this purpose we require such an instrument as the sextant, for measuring the altitudes and taking the distances of the heavenly bodies; and a chronometer, to tell us the difference in time between the meridian of the ship and the first meridian; also a precalculated astronomical register, such as our "Nautical Almanac," the "Connaissance des Temps" of France, or the "Berlin Ephemeria." The solution of problems relative to the celestial concave requires the use of spherical trigonometry, which, therefore, characterises in a marked manner this method of navigation. The process of estimating a ship's place by these means is called technically "By Observation," in contradistinction to "By Dead Reckoning" Celo-navigation for voyages away from land is more ancient than geo-navigation (Acts xxvii 20). Celo-navigation has been commonly called "nautical astronomy"; but this term implies a branch of the science of astronomy, just as "nautical geography" would imply a branch of the science of geography, whereas we wish to speak of a branch of the science of navigation. We therefore suggest the adoption of the terms "Geo-navigation" and "Celo-navigation" in the place of "navigation" and "nautical astronomy"; the generic word always: being "Navigation"-See further under each term. both the above methods are combined.

Neap Tides (Sax. neafte, "scarcity").—The smallest tides. They take place after the sun and moon are in quadrature—i.e. after the first and third quarters of the moon—and are the tides resulting from the action of the two bodies conflicting. Contrasted with the neap are the spring tides—See Tides.

Needle—The magnetised bar of steel in the mariner's compass; the earliest form (that used by the Chinese) being a light thin wire like a "needle." What form is best has been a matter of controversy, the highest authorities favouring the regular parallelop.ped with its narrow dimension placed vertically. The question of neight is also important; it seems to be generally true that the magnetic power increases in a less degree than the the friction with the increase of weight. Agate or ruby caps to the pivot are used to diminish the friction

Nimbus (L. "The Ram Cloud"). - Regarded by Howard as one of the combined modifications of cloud, and called, the Cumulo-curro stratus; but considered one of the primary classes by Fitzroy. -See Cloud.

Noon (Sax.). According to the kind of time considered, noon is the instant when the "point of definition" is on the meridian of the observer. Thus when solar time is used, Apparent Noon is the instant when the sun's centre is on the meridian of the observer; Mean Noon is when the mean sun is on the meridian. Noon is regarded as the commencement of the astronomical day, as midnight is made the commencement of the civil day.

Normal (L, normain, from norma, "the square" used by builders). -Perpendicular. The term is used in geometry for the perpendicular to the tangent of a curve or plane at any point,

Normal Latitude. The angle which the normal to the earth's surface at the station of the observer makes with the plane of the equator; distinguished from the central latitude.

Normal Centre — The point on the earth's axis at which the vertical from the place of observation meets the earth's axis. If I be the latitude of the place of observation; then,

Normal centric radius = equatorial radius  $\times$  (1 +  $\frac{1}{300}$  sin<sup>2</sup> !). Reference to this point is considered by Airy the most satisfactory way of 1 cating the earth's oblateness. He applies the method in computing the corrections in lonar distance observations.

North Point of the Horizon -The north and south points of the horizon being the points in which the meridian line meets the celestral horizon, the north point is that which is nearest to the north pole of the heavens.

North Pole of the Barth. (Sax nord).—The pole to which Europe is most contiguous; the other being the south pole.

North Pole of the Heavens - That pole of the heavens towards which the north pole of the earth is directed; the point diametrically opposite to it being the south pole.

North Frigid Zone. —That zone of the earth which is contained between the north pole and the arctic circle (parallel of about 66° 33′ N ).

North Temperate Zone.—That zone of the earth contained between the tropic of Cancer (parallel of about 23° 27' N ) and the arctic circle (parallel of about 86° 35 N.).

Northern Hemisphere. —Of the two hemispheres into which the earth is divided by the equator, the northern is the one in which Europe is situated, the other being the southern.

Northing -The distance a ship makes good in a north direction; it is her difference of latitude when going northward. Opposed to southing

Nutation. - See Precession and Nutation.

0.

Of the letters used to register the state of the weather in the log book O indicates "Overcust—i.e. the whole sky covered with one impervious cloud."

Oblate Spheroid (L. oblatus, "compressed").—A spheroid flattened or depressed at the poles; it may be conceived to be generated by the revolution of an ellipse about its minor axis. This is the form which a mass of fluid matter rotating on an axis assumes, and is important as being consequently the figure of most of the heavenly bodies.

Oblique Sailing.—By modern writers this term is generally used as synonymous with "Oblique Triangles applied to Sailing," and treating of problems such as are concerned with the motions of more than one ship, as in making a rendezvous, ornising and chasing, the solution of which involves oblique angled triangles. But the proper application of the term rests on its distinction to Right Sailing. To quote Sir Jonas Moore's Work, (1582)—"Navigation or Sailing in respect of the Rhumb or Point sailed on is aptly divided into Right and Oblique. Right Sailing is when the voyage is performed on

some one of the four Cardinal Points. Oblique Sailing is what ship runneth upon some Rhumb between any of the four Cardinal, making an Oblique Angle with the Meridian." The standard of the problems in Oblique Sailing (in this sense) is accomplished aid of the right angled triangle: Right Sailing does not even a right angled triangle. See Cardinal; Rhumb.

Oblique Sphere.—The sphere in that position in who circles apparently described by the heavenly bodies in their rotation are oblique to the horizon. It is thus that the motions to all parts of the earth, except at the poles and the equator oblique sphere is distinguished from the right sphere and the sphere.

Obliquity of the Ecliptic.—The angle at which the is inclined to the equinoctial, and which is, therefore, the determinant the subject to a small ation of long period; on the 1st of January, 1896, it was 23° 2′ It follows that the axis of the earth, which is perpendicular plane of the equinoctial, is inclined to the plane of her orbinangle of 66° 32′ 42″·2, the complement of the obliquity. It obliquity of the ecliptic which is the cause of the variation seasons. [See Seasons.] It is also one of the causes of the solar day.—See Day.

Observed Altitude.—The observed altitude of a he body must be distinguished from the apparent altitude and taltitude.—See under Altitude.

Observed Distance.—The observed distance of two he bodies must be distinguished from the apparent distance and t distance.—See under Distance.

Occultation (L. occultatio, "a hiding") -The hiding of a heavenly body from our sight by the intervention of some other heavenly body. The commencement of the occultation, the moment when the occulted body disappears behind the nearer one, is called the Immersion (L. immergère, "to plunge in"); the termination of the occultation, the moment when the occulted body reappears, is called the Emersion (L. emergère, "to come out"). [See Eclipse ] The two most important cases of these phonomena are the I weer Occultations and the Occultations of Jupiter's Satellites. Particulars for each year of the occultations of the planets and fixed stars by the moon will be found in the "Nautical Almanac" in tables called "Elements of Occultations," and "Occultations visible, etc., at Greenwich": tables and diagrams for the occultation of his satellites by the planet Jupiter are also given in the "Nautical Almanac," Occultations belong to that class of phenomena which furnish a means for determining the longitude - See under Longitude,

Octant (L. octans "the eighth part") —A reflecting sector, the limb of which is the eighth part of the circle.—See Sector.

Ophiuchus (Gk. δφισίχοι, "serpent holder"; from δφιι, "a serpent"; έχειν, "to hold"; L. serpentarius, A constellation to the north of Scorpio; the largest star, a Ophiuchi, forms with Lega and Altair an equilateral triangle. Mag 2.2: N.A. 1896, R.A., 17h 30m, Dec. + 12° 38'

Opposition —Two celestial bodies are said to be in opposition when their longitudes differ by 180°. Symbol & Opposed to conjunction.

Orion (named after a mythical grant hunter). The most brilliant constellation of the heavens, figured as a man with club and hon's skin. The stars  $a, \beta, \gamma, \kappa$ , are in the form of a great quadrilateral  $\gamma$ .

a at the north east angle being in the right shoulder of Oric nearest to the Twins; β at the opposite angle in the left for the left shoulder; and κ is in the right leg. In the mi quadrilateral are three stars of about the second magnitudisposed in an oblique line; these form the belt of Orion, i depends a luminous train of small stars, called the swe constellation is surrounded by a series of the most conspiring the heavens—Aldebaran, Capella, Castor, Pollux, Proc; and Canopus. The equinoctial crosses near its middle. (Arabic name, Betelguese or Betelguer), Mag. (var.) 1.0 to R.A. 5h 50m, Dec. + 7°23'. β Orionis (Arabic name, R 0·3, 1896, R.A. 5h 10m, Dec. - 8°19'. δ Orionis, Mag. (var.) 1.0 to 1896, R.A. 5h 27m, Dec. - 0°23'. c Orionis is the r of the belt, Mag. 1·8; 1896, R.A. 5h 31m, Dec. - 1°16'.

Orthographic Projection Gk. optos, "straight" to grave").—The orthographic projection of the sphere i projection made by straight lines at right angles to the p plane of projection. The eye is conceived to be infinit from the sphere, so that the visual rays are parallel to or and a diametral plane is chosen for the primitive.—

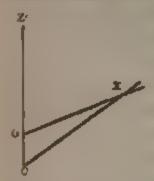

Projection.

P.

p.—Of the letters used to register the state of the the the log-book, p indicates "Passing showers."

Pamperos.—Winds blowing off the Pampas, the diplains of the south-east of South America. The nambelongs to every south-westerly wind on this coast, but usage generally restricts it to violent westerly squalls w times rotate.

Parallax Gk. παράλλαξα, "afteration," "the mutual melination of two lines forming an angle").—The apparent angular shifting of an object arising from a change in our point of view. It is expressed

by the angle subtended at the object by a line joining the two stations. Thus, let X be the object, O and C the two points of view; then the difference of the angular position of X, with respect to the invariable direction ZOC, when viewed from O and from C, is the difference of the angles Z'OX and Z'CX; but OXC = Z'OX - Z'CX (Euc : 32), i.e. the angle subtended at X

by OC measures the apparent angular displacement of the body resulting from the change of the observer's point of view in moving from O to C. It is evident that the nearer the object the greater will be the amount of parallactic motion for any given change of the point of view. When the distance is very great in comparison with the change of the observer a station, the parallax is inappreciable, the place of the object not appearing to vary.

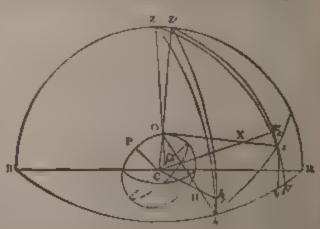

In astronomy the term parallax has a more technical meaning than the above. The apparent place of certain of the heavenly bodies is different as seen from different stations. It therefore becomes necessary, in order that observations made at various stations may be generalized, and put into a state to admit of the rosing compared with one another, that some conventional station should be fixed upon to which they may all be reduced. Parallax is defined as the correction to be applied to the apparent place of a heavenly body, as actually seen from the station of observation, to reduce it to its place as it would have been seen at that instant from the conventional

station There are two of these conventional centres, which are used in different cases for different purposes—the centre of the carth, and the centre of the sun. The correction for reducing the apparent place of a heavenly body as seen from the surface of the earth, to what it would have been had the observer been stationed at the centre of the earth, is distinguished as the Geocentric or Diurnal Parallex. The correction for reducing the apparent place of a heavenly body as seen from the earth in any position of her orbit, to what it would have been had the observer been stationed at the centre of the sun, is called the Heliocentric or Annual Parallex. With this latter the practical navigator has no concern,

Parallax. Geocentric or Diurnal -This is the correction to be applied to the apparent place of a heavenly body as actually seen from the station of the observer on the earth's surface, to reduce it to its place as it would have appeared at that instant if viewed from the earth's centre. Hence it is called the Geocentric Parallax; it is also entitled the Diurnal Parallax, because it goes through its

course of variation, within the time the body is above the horizon.

Let X be the heavenly body under observation, O the station of the observer on the earth's surface, C the earth's centre; let Z' be

the reduced zenith of O, then the line ZOC is the invariable direction

with respect to which the apparent angular change of position of X is referred. The place of X on the celestial concave as seen from O is  $x_i$ , and its place as seen from C is  $x_i$ , a point in the great circle joining Z' and x in position above the point  $x_i$ . Then the angle OXC (-p) is the parallax of X; and since, in all cases where the geocentric parallax is appreciable, the distance of the body X vanishes compared with the distance of the celestial concave, the angle OXC  $(-xXx_i)$  are  $xx_i$ , therefore, in speaking of the parallax, either the angle OXC, or the ore  $xx_i$  may be taken to represent it.

Let r=CO, the distance of the observer from the centre of the terrestrial spheroid; D=CX, the distance of the body X from the same centre; z' the apparent reduced zenith distance of X;—then, in the triangle COX,

$$\frac{\sin OXC}{\sin COX} \cdot \frac{CO}{CX}$$

$$\sin p = \frac{r}{D} \sin z' \quad , \quad , \quad , \quad (a)$$

The parallax is generally so small that, except for the moon, no sensible error is introduced by using the circular measure for the sine :

In the particular case of the body appearing in the horizon of the observer, the corresponding particular value of the diurnal parallax is called the *Haricontal Parallax* (- P); here z' 90°;

: sin P or (nearly) 
$$P = \frac{r}{D}$$
 . . . . (7)

and substituting this value of  $\frac{r}{D}$  in equation  $(\beta)$  we get

which is the parallax at the apparent zenith distance z', in the horizontal parallax and that zenith distance.

Again, let a be the radius of the earth at the equator, e the tricity of the elliptic meridian of the earth, l the latitude of whose horizontal parallax is P, and let P<sub>e</sub> be the Equatorial Ho Parallax, then—

$$P_{e} = \frac{a}{D}$$

$$\therefore P = \frac{r}{a} P_{e}$$

$$= P_{e} \sqrt{1 - e^{2} \sin^{2} l}$$

From the above formulæ the following conclusions are drawn from  $(\gamma)$  it follows that the nearer the body the greater will parallax. (2) For the same body  $(\beta)$  shows that the parallax as the sine of the apparent zenith distance; and hence, also has a course of variation comprised within the the time the above the horizon. (3) From a comparison of  $(\beta)$  and  $(\gamma)$  it that parallax is greatest when the body is in the horizon observer, and that it vanishes when the body is in the zenith. (4) The earth's radius diminishing from the equator pole, we conclude from  $(\epsilon)$  that the horizontal parallax decrete latitude of the observer increases.

Parallax, Horizontal.—The horizontal parallax is a ticular value of the diurnal parallax when the body app the observer's horizon. It would be a great improvement if a Horizon Parallax could be substituted for "horizontal parallax the latter has the authority of the "Nautical Almanac." be the position of the body X in this case, h its place in the as seen from O, and he (a point in the great circle passing the

and Z') the place of the body in the celestial concave as seen from C; then the angle OHC, or the arc  $hh_{\theta}$ , is the horizontal parallax (P). The angle COH is a right angle,

$$\therefore$$
 sin P or (nearly) P  $\Rightarrow \frac{r}{D}$ 

a formula which we deduced from the general one ( $\beta$ ) of the last article by making  $z' = 90^\circ$ . It also appeared that the horizontal parallax is the greatest value of the diurnal parallax. Again it was shown that p, being the value of the diurnal parallax when the apparent zenith distance of the body is z.

from which p may be calculated when P is known. But as the radius of the terrestial apheroid varies with the latitude of the observer, it is necessary to specify some standard value of P before it can be available for general use; this value is the Equatorial Harizontal Paratlax ( 1, 1, ). Hence, from (i), last article,

 $\sin p$  or (nearly)  $p = P_e \sqrt{1 - e^2 \sin^2 l}$ ,  $\sin z'$ 

Thus, for example, the moon's normontal parallax given in the "Nautical Almanae," p. 111, is the equatorial horizontal parallax. For any other place a subtractive correction must be applied to this which is taken from a table given in works on navigation.

Parallax in Altitude.—The parallax in situade is the parallax as it affects the altitude of the body under observation. Strictly, the diurnal parallax takes place in the great circle passing through the apparent place of the body and the reduced zenith (as  $Z'x_{\nu}V'$ ), parallax in situade is supposed to take place in the great circle passing through the apparent place of the body and the true zenith (as the vertical circle ZxV). Since, however, these two circles  $(Z'x_{\nu}V')$  and  $Z_{\nu}V'$  are nearly coincident, and as the parallax  $(x_{\nu}v')$  in

small, the diurnal parallax may be used without error for the parallax in altitude in all the common problems of cele-navigation. Formula (5) thus becomes

Parallax in altitude = horizontal parallax × cos altitude.

The altitude here is first corrected for refraction. From this formula tables have been computed sufficiently accurately for correcting the apparent altitude of the sun and the moon for the combined effects of parallax and refraction.

Parallax being supposed to take place in vertical circles, the term Parallax in Altitude is often used, in contradistinction to the Horizontal Parallax, to signify any value of the diurnal parallax except that which it has when the body is in the horizon.

## Parallax of Sextant. -- See Sextant.

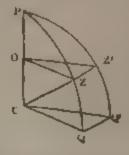

Parallel Sphere — The sphere in that position in which the circles apparently described by the heavenly bodies in their diurnal revolution are parallel to the horizon. This can only happen to a spectator at the poles. The Parallel Sphere is distinguished from the Right Sphere and the Oblique Sphere.

Parallels of the Sphere.—Small circles whose planes are parallel to the primitive great circle in any system of co-ordinates each thus marks out all points which he at the same distance from it. On the terrestrial sphere the Parallels of Latitude are small circles parallel to the equator, and each marks out all places that have the same latitude north or south. On the colestial sphere, Parallels of Declination, Parallels of Latitude and Parallels of Altitude are small circles whose planes are parallel respectively to the equinoctial, the ecliptic, and the horizon, and in each case mark on

respectively all points that have the same declination, the same latitude, or the same altitude. See Co-ordinates for the Surface of a Sphere.

Parallel Sailing. -- When the ship's track hes along a parallel of

latitude. In this particular case the three canons of plane sailing are unnecessary as distance = departure, and course = 90°; but further, it is a case of spherical sailing, for the complete solution of which plane trigonometry suffices. The latitude being constant, the difference of longitude bears a constant ratio to the distance, and

all problems may be completely solved by the solution of a rightangled plane triangle, and therefore by inspection of the traverse table.

Parallel sailing may be considered as the link between plane and apherical sailing; its characteristic formula is

Distance difference of longitude x coaine latitude.

This may be proved as follows :-

Let Z and Z' be two places, P the adjacent pole, ZZ' the arc of the parallel of latitude passing through the two places, QQ' the corresponding arc of the equator intercepted between their meridians. Then the sectors CQQ', OZZ' being similar,

$$\frac{ZZ'}{QQ'} = \frac{OZ}{CQ} = \frac{OZ}{CZ'} = \sin OCZ = \cos QCZ$$

. ZZ' QQ'. cos QZ, or, Dist. = diff. long. x cos lat. which, in logarithmic form, is-

log. dist. = log. diff. long. + L cos lat. - 10

The method of parallel sailing will apply correctly enough practical purposes to cases where the course is nearly east of In latitudes not higher than 5°, when the distance does not 300 miles, the departure may be used at once for the differentiation, the resulting error scarcely exceeding one mile, the means of determining the longitude were not so reliable are now, it was a common practice first to make the parallel place of destination and then sail along it east or west as represented the importance formerly attached to parallel sailings.

Parallelogram of Forces. —The most important proin mechanics, and one which the navigator has constantly to

A single force which is capable of producing the same efficient or rigid body as would result from the combined ac several other forces, is called their resultant, and the constrorces of the system with reference to this equivalent result called components.

The Parallel gram of Forces may be thus enunciated: If twacting at a point be represented in magnitude and direction atraight lines drawn from that point, and if a parellelog constructed, having these two lines for adjacent sides, the diagonal of the parallelogram which passes through the parallelogram of the forces will represent their resultant in mand direction.

The components are generally described by the letters P and the resultant by R. As the opposite sides of the parallel are equal and parallel, and the opposite angles equal, problet treated by the solution of a plane triangle. A few examples mentioned.

I The wind acting on a flat sail is R, and it may be resolved into P acting perpendicular to the surface of the sail and propelling the ship, and Q acting along the surface and producing no effect.

The component P may be again resolved into two sub-components, one urging the ship forward in the direction of her length, the other causing her to make leeway.

- 2. The effects of a steam propeller of a vessel may be represented by P, and the action of the wind by Q; the combination will result in R.
- 3. The combined effect of the oars of a beat may be called P, and the action of the current Q; the resulting way of the boat will be R.
- 4. The magnetic influence of a ship upon a compass needle may be represented by a single force R, and this may be resolved into two components, one P acting horizontally, and the other Q acting vertically.

Again the horizontal component may be further resolved into two sub-components, one acting fore and aft, the other athwartships

5. A similar principle applies to velocities, an illustration of which will be found in aberration.

Pavo (L. "The Peacock"). — An unimportant constellation to the south of Sagittarius, lying between the two bright stars Antares and Fomalhant. The northernmost star is a Pavonis; Mag. 2.1; 1896, R.A. 20h 17m. Dec. — 57° 4′.

**Pegasus** (named after a mythical winged horse of the Greeks). —A constellation, the tour principal stars of which a,  $\beta$ ,  $\gamma$ ,  $\delta$ , form a remarkable square;  $\delta$  Pegasi is also called a Andromedo, and the two other stars of Andromeda,  $\beta$  and  $\gamma$ , together with the

adjoining  $\beta$  Persei, form, with the square of Pegasus, a group very similar to, though much more extensive than, the Great Bear lying on the opposite side of the pole. Cassiopeia lies about midway between Polaris and Pegasus. a Pegasi is the furthest from Andromeda and the westernmost of the constellation, therefore passing the meridian first, and  $\beta$  is at the northern angle. There are two small stars  $\gamma$  and  $\xi$  which are parallel to this side of the square and serve to identify it. a Pegasi (Markob), Mag. 2.6, 1896, R.A. 23h 0 n Dec. + 14° 38.  $\gamma$  Pegasi (or a Andromeder), Mag. 2.1; 1896, R.A. 0h 3m. Dec. + 28° 31'.

Pelorus. - A dumb-card matrument for assisting to ascertain the deviation of the compasses on board ship, and to set the course. constructed and patented by Lieutenant M. C. Friend, R. N., and W. Browning, in 1854. It may either be fitted to the compans or used on a separate stand. The instrument is to all intents and purposes what is more commonly called in the Service a Bearing Plate. The appellation chosen by its patentees is interesting, especially as we have a ship of the same name. Pelorus was the N.E., cape of Trinacria or Sicily. It was always an important land-mark for sailors, being near the dangers of Charybdia, and on it stood from very ancient times a celebrated temple of Neptune fabled to have been built by Orion. It is now called Cape di Fare, " Light house Cape." Its old name is said to have been given to it by Hannibal after the pilot of the ship in which he sailed from Italy. Believing that Pelorus had falsely told him that the Cape was in Sicily and not a part of the mainland, and that his intention was to betray him to the Bomans, the Carthagenian General put him to death, but on finding that he had spoken the trath he honored his memory by calling the promontory after him. The name of the faithful pilot is an appropriate term for a card deprived of its living magnet, but which helps to direct us on our course.—See Compass-Card, Bearing Plate.

Perseus (named after a mythical hero, the slayer of Medusa).— A constellation lying between Auriga and Taurus on its east, and Cassiopeia and Andromeda on its west. Of its two principal stars, a lies nearly between Capella and Cassiopeia, \$\beta\$ (also called \$\beta\$ Medusa) forms a triangle with Capella and the Pleiades. \$\beta\$ Persei is remarkable for its periodic changes of magnitude from 2.25 to 4 in a period of ten days. \$\alpha\$ Persei, Mag. 1.9; 1896, R.A. 3h 17\alpha\$, Dec + 49° 29'.

Personal Error or Equation.—Different individuals have their peculiarities which materially affect the observations made by them. The organ of vision is more refined and specially educated in one person than in another, and the forming a judgment of the exact instant of a phonomenon is greatly influenced by the temperament of the observer. The error arising from this cause is called the Personal Error, or, with reference to the consequent correction to be made to an observation, the Personal Equation Even when two images in contact are at rest before two observers, one will decide that they overlap, and the other that they are apart; but especially when the images are in motion does such difference of opinion occur. Anxiety lest he should miss the observation may lead a nervous observer to think he sees the contact before it really takes place, while quickness of perception may be deficient in another observer. It is also found that the personal equation is not constant for the same individual at all times, but is influenced by any cause which affects the nervous system, especially the fatigue of continued observing.

accuracy is required, these circumstances should be borne in preparatory to observing; and observations taken by different p should not be used in combination until cleared of the personal Such corrections as this are of a refined character, and are regonly in observations made on shore in an observatory.

Phases (Gk.  $\phi d\sigma vs$ , "an appearance").—The different a ances presented by the moon, the inferior planets, and Maconsequence of varying portions of the disc, seen from the being illuminated by the sun's rays.—See under Moon, Venu

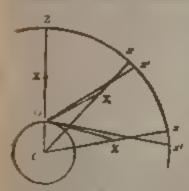

Phoenix (named after a mythical bird of the Egyptian constellation the principal star of which, a Phænicis (Mag. 2 situated midway between Fomulhaut and Achernar, nearly in t joining them.

Piscis Australis (L. "The Southern Fish").—A consteto the south of Aquarius, containing the brilliant star Fomalhaut. A line through  $\beta$  and a Pegasi, continued mortwice their distance, gives the position of a Piscis Australiance, gives the posi

Place, Geocentric and Heliocentric.—By the Planewenly body is meant the point on the celestial concave to we is referred by a spectator. This place will evidently differ accept to the spectator's point of view. For the sake of generobservations, and putting them into a form fitted for comparise turning them to practical account, it therefore becomes need to agree upon some conventional centre, and reduce all observations at various stations to what they would have been had the made at this centre. There are two such conventional stations by astronomers—the centre of the earth, and the centre of the

The place of a heavenly, body as viewed from the centre of the earth, is called its  $Geocentric\ Place\ (\gamma\hat{\eta},\ ''$  the earth ''); the place of a heavenly body, as viewed from the centre of the sun, is called its  $Heliocentric\ Place\ (\hat{\eta}\lambda ios,\ ''$  the sun '') —See Parallax.

Place. Apparent and True.—The Apparent Place of a heavenly body is the point on the celestial concave to which it is referred by an observer from a station on the earth's surface viewing it through the atmosphere. The True Place of a heavenly body is the point on the celestial concave to which it would be referred by in observer at the centre of the earth viewing it through a uniform medium. Let C be the centre of the earth, O the observer's station,

X a heavenly body. Draw O. the tangent to the visual ray from X meeting the celestial concave in x, and join CX and produce CX to meet the celestial concave in x; then the projections x and x are respectively the apparent and true places of X. They differ most when the body is in or near the horizon, and coincide when it is in the senith. The

true place is obtained from the apparent place by applying the corrections for refraction and parallax, the former of which causes a body to appear higher, the latter lower than its true place. These two corrections are thus combined, but the difference in the nature of refraction and parallax must not be therefore forgotten; in consequence of refraction the object is not actually in the position in which it seems to be; parallax is merely a reduction of the observations made at one place to what they would have been if made at another. Refraction is independent of the distance of the body, but parallax increases with the proximity of the body.

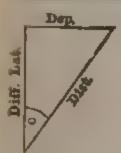

body is very near, like the moon, parallax tonds to depress more than refraction to raise, and therefore the moon's apparent place is lower than her true place. On the convery, for more distant bodies, such as the sun and planets, refraction raises more than parallax depresses, and therefore the apparent place of these bodies is higher than the true place.

## Place of Ship . See under Position

Plane Chart — A chart constructed on the supposition that the cach is an extended flat surface. The meridians are depicted as parallel right lines, and the parallels of latitude at right angles to the meridians; the length of degrees on the meridians, equator, and parallels of latitude are everywhere equal, the degrees of longitude being reckoned on the parallels of latitude as well as on the equator. It is define ation represents very nearly the relative directions and distances of places near the equator, and serves for plans of porta and seas in those regions. For higher latitudes it exhibits truly no directions but N and S, E, and W., and no distances but those measured on the meridian, and hence the figure of every portion of the surface, however small, is distorted. The use of these charts is obsolete.

Plane Sailing The method of solving, or partially solving, problems in mavigation by means of the formulæ of plane trigonometry, it is opposed to spherical sailing, which takes account of the elements affected by the spherical form of the earth's surface. Plane sailing requires the use of plane trigonometry only; spherical sailing calls in the aid of spherical trigonometry, either in the actual computation or in the construction of the tables used. The two general problems of paragration are: 1st. Given the latitudes and longitudes of two

places, required the course and distance from one to the other; and 2nd, Given the latitude and longitude of a place, and the course and distance from this to another place, required the latitude and longitude of the latter. If we attempt completely to solve these problems on the principles of plane sailing, a place chart must be used and a chart in which the meridians are depicted as parallel right lines, the parallels of latitude drawn at right angles to the meridians, and the length of the degrees on the meridians, equator, and parallels of latitude are everywhere equal, the degrees of longitude being reckoned on the parallels of latitude as well as on the equator. The results thus obtained would be very arroneous, except where the track of the ship lay near the equator. If however, besides the above elements—course, distance, difference of latitude, and difference of longitude—we introduce another, the departure, the problems of navigation may in every case

be solved to a certain point on the principles of plane sailing. In thumb sailing, the course being constant, the difference of latitude and departure are proportional to the distance on the sphere as they would be on a plane; these three elements may therefore be represented by the adea of a right-angled plane triangle, of which one of the angles is the course. Hence, in the general

solution of the problems of navigation, plane sading furnishes us with the following relations between the course, distance, difference of latitude, and departure, which are sometimes called the "Canous of plane sailing":

- I. Dep. = dist. x san course
  - A log dep. log dist. + L sin course + 10.
- 2. Diff lat. = dist. x cos course

. log. diff. lat. - log. dist. + L cos course - 10.

3 Dep. = diff. lat. x tan course

# log. dep. = log. diff. lat. + L tan course - 10.

The solution of a right angled triangle, of which these quantities are the cloments, may be effected by inspection by the use of the Training There is, however, no constant proportion between the departure and the difference of longitude in different latitudes; and, therefore, problems in which difference of longitude is concerned are beyond the province of plane sailing, except when the ship is near the equator, where the departure and difference of longitude may be for practical purposes considered equal. The principles of plane sailing are conveniently applied in coasting or making land, when a plane chart may, without error, be used. It enables us at once to resolve the distance run on any given course into the distance upon a proposed. course, and thus to determine, for instance, the rate at which a ship is approaching a proposed port. When the ship makes several courses in succession, we have what is called Traverse Sailing, which consists in finding a single resultant for the several courses and In Current Sailing a resultant has to be found for two distances. simultaneous courses and distances. Oblique Suiling is a term applied to those cases for the determination of which an oblique triangle has to be solved. The above is the accurate use of the term "Plane Sailing," but it is sometimes loosely used as a synonym for the equally ill used term "Navigation," as contrasted with "Nautical Astronomy " It is thus made to include "Mercator Sading"; but although Mercator sailing apparently requires the application of plane trignometry only, the table of meridional parts, the use of n sich characteriaes it, involves the principle of the sphere. The term plane sailing should be restricted to its proper signification. -

See Sailings.

Planets (Gk. dorne wharters, "a wandering star," from This term originally described all the heavenly bodies which were observed to change their place in the celestral concave, in contradistinction to those whose position appeared to be fixed. The word, however, is now technically restricted to indicate those moving bodies of a character similar to our own globe, which revolve in orbits about the sun of our system. They shine by the reflection of light received from the sun principal planets, in the order of their distances from the sun, with their symbols, are - Mercury 5, Venus 9, the Earth @ or 8, Mars Jupiter 4, Saturn h, Uranus #, Neptune 4. Besides these, near to the sun a small planet named Vulcan has been reported, and between Mars and Jupiter is a group of minute planets, called the Asteroids or Planetouls; they are very numerous, between eighty and ninety having been already detected and named. The paths of the principal planets are in planes making a small angle with the plane of the ecliptic. The planetary motions are governed by the three following laws, called, after their discoverer, Kepler's Laws: (1) The planets move in ellipses, each having the sun's centre in one of its foci; (2) The areas swept out by each planet about the sun are in the same orbit, proportional to the time of describing them; (3) The squares of the periodic times are proportional to the cubes of the major axes. It must, however, be borne in mind that, strictly speaking, the centre of the sun is not a fixed point, the motion taking place about the centre of gravity of the whole system; this point, however, is very near the centre of the sun. Again, the planets mutually attract each other, and this causes perturbations of their several orbits

To the practical navigator the actual dimensions and movements of the planets are not so important as the conspicuous phenomena

they exhibit. Four of them - Venue, Mars, Jupiter, and Saturnare remarkably large and brilliant bodies, and of great importance in the problems of cele-navigation; another, Mercury, is also visible to the naked eye as a large star, but by reason of its propinguity to the sun, is seldom conspicuous; Uranus is barely discernible without a telescope; the rest are never visible to the naked eye. Venus and Jupiter are seen very distinctly during twilight, and this is the best time for observing them, for then the horizon is in general clearly visible and strongly marked. Observations of these two planets may often be obtained in the daylight, even when the planets are invisible to the naked eye. The meridam altitude of Jupiter may sometimes be thus observed with advantage. It is first approximately computed-the corrections for refraction, dip, and index-error being applied reversely; this angle is then set on the sextant, the inverting telescope being screwed close down to the plane of the instrument. The image of the planet will be by this means detected near the N. or S. point of the horizon, and, once found, its meridian altitude may be accurately observed. The four planets, Venus, Mars, Jupiter, and Saturn, are used for determining the longitude by the method of "lunar distances," It is, therefore, important toknowhow to identify these bodies. They are collectively distinguished from the fixed stars by their shining with a steady light, instead of twinkling. reason of their proper motion they are continually shifting their place in the celestral concave, and cannot be connected by imaginary lines with other heavenly bodies, as in the cases of the fixed stars. Their position at any time may, however, be found with the aid of the "Nintical Almanac," which gives their right ascension. declination, and the time of Greenwich meridian passage. We may here fuel tre planet's meridian attitude at the time of its transit over the merianan of observation, or we may find in what constellation it is situated, or ascertain its position with respect to some bright star near it at the time. The appearance of the body itself may also help to determine which planet it is: Venus has a bluish light, while Mars is of a red colour. Venus and Jupiter are the brightest: but the former, which is an inferior planet, is never seen more than 47° from the sun, while Jupiter is seen at every distance from the sun.

Planets, Inferior and Superior. Those planets whose orbits are within that of the earth are called Inferior Planets; those whose orbits are external to that of the earth are called Superior Planets. The inferior planets are Vulcan, Mercury, and Venus; the superior planets are Mars, the Asteroids, Jupiter, Saturn, Uranus, and Noptune. The phenomena exhibited by these two classes, to an observer on the earth's surface, are in many respects different. The changer in. or the angle subtended at the earth by a planet's distance. from the sun, in the case of the inferior planets can never exceed a certain limit. Mercury, owing to its nearness to the sun is sendom visible; Venus, when to the west of the sun, is seen in the cast a little before sunrise, and is then called the Morning Star; at other times, when to the east of the sun, it is seen in the west just after annaet, and is then called the Evening Star. There is, on the other hand, no limit to the elongation of the superior planets, and therefore no connection between the times of their rising and setting and that of the sun; they are seen at all hours of the night, and at various altitudes above the horizon. Again, a trummt over the sun's disc can only occur in the case of an inferior planet. And, finally, the inferior planets present to the earth phases like those of the moon; the superior planets (with the exception of Mars, which sometimes presents a slightly gibbous appearance) have no perceptible change of phase All the planets, as seen from the curth, are alternately

appears to be moving forwards ("direct," in the order of the signal when in the conjunction furthest from the earth; and backwards ("retrograde," contrary to the order of the signs) when in the conjunction nearest to the earth. Similarly a superior planet always appears to be moving forwards when in conjunction, and backwards when in opposition.

Planets, Primary and Secondary.—In the solar system there are at least twenty moons or satellites, and these are sometimes called Secondary Planets; hence the planets themselves about which these revolve are distinguished as Primary Planets. The two an planets and Satellites are the most convenient names for the two classes of bodies.

Pleiades (Gk wheddes).—A very conspicuous cluster of seven small stars, and of which are visible, in the constellation Taurus. This group is a very convenient mark to help the seaman in identifying bright stars in its vicinity. It is also of historical interest to the navigator. The ancient astronomers connected the seasons with the position of stars relatively to the sun at his rising and setting a star was said to rise heliacally (hhis: "the sun") when after being to conjunction with the sun, and consequently invisible, it rises so much before him as to be visible in the eastern horizon in the morning twilight; and it was said to set heliacally when the sun approaches so near to it that it is extinguished in his light or ceases to be visible in the western horizon after he has disappeared. The word Fleiades is derived from when "to said the sea," because the season of threely navigation began at its heliacal rising.

P.M.—The initials of Post Merudiem (L.), "after noon"; opposed to A.M., Ante Meridiem, "before noon."

Pointed Sun.—When an observation is taken with a reflecting sector, the sun seen by direct vision is called by Raper and others "the pointed sun"; a better term is "the direct sun.

**Pointers.**—The two bright stars  $\beta$  and a Ursa Majoris, are called the "Pointers," because they point out Polaris, which has at about the same distance from a as a does from  $\eta$ , the extreme star in the tail of the Great Bear.

Points of the Compass.—The circumference of the compasscard, which represents the horizon of the spectator, is divided into 32 equal parts called points. As in the whole circumference there are 360°, there are in each point 11° 15′. The point is sub-divided into Half points (each 5° 37′ 30″) and Quarter-points (each 2° 48′ 45″).

Polar Angle -On the terrestrial sphere, the angle at the pole formed by two meridians; on the celestial sphere the angle at the pole formed by two hour-circles.

Polar Circles. The two parallels of latitude enercling the poles at the same distance from them that the tropics are from the equator—viz. about 23° 27; they are, therefore, the parallels of about 66° 33 N. and S. We say "about," because their positions go through small periodic changes. The North Polar Circle is called the Arctic Circle, from the great constellation which is situated within the parallel of declination of about 66° 33 N.—the "Bear" (Apares); and the South Polar Circle is distinguished as its opposite, the Antarctic Circle. They mark the hints of those zones within which the sun does not set in the interval between at least two or more consecutive culminations. These spaces are called the Frigid Zones, and are divided by the polar circles from the Temperate Zones.

Polar Distance - The polar distance of a heavenly lody is its angular distance from the elevated pole of the heavens; it is measured by the intercepted are of the hour-circle passing through it or by the corresponding angle at the centre of the sphere. Noted times polar distances are reckoned from the nearest pole from 0 🐙 90°, but this plan is attended with inconvenience Agam, the policy distance is the complement of the declination, and declinations frequently regarded as positive ( + ) or neg tive ( ) according as the object is estuated in the northern or southern celestial hemisphere ; it this case, all ambiguity is avoided by reckoning polar distances from the north pole from 0 to 180. But the most convenient meti-al a reckoning polar distances is from the elevated pule towards the lepression one from 0" to 180". According as the north or south pole is elevated we have the North P lar Distance or the South Polar Distance The hour angle and polar distance are the polar co ordinates for defining points of the celestial concave, and indicating their position relatively to the place of an observer on the earth's surface. Said Hour-Angle and Polar Distance.

Polaris (L., understand Mella, star) or Pole Star — The polstar of a planet is the bright star towards which its axis of rotations directed at any epoch. With reference to the earth the star Ursac Minuris is so called from its being the bright star was his nearest to the north pole of the heavens. Its Arabic name is Ruccabah, and it is also known as the Cynomics (from whee, "a size and objec, "the tail" the constellation of Ursa Minor being and ently figured as a dog). Polaris can readily be found by the line of their direction passes. a Ursac Majoria (Dublie) is at the same distance from the stars in the extremities of the two consti-

lations, the Great Bear and the Little Bear, the former being n Urset Majores, and the latter a Urac Minores or Polaris The star a Urac Minor is has not always been and will not always continue to be the Pole star. The precession of the equinoxes involves a very slow motion of the pole of the heavens among the stars in a small circle round the pole of the ecliptic. The effect of this is an apparent approach of some stars to the pole while others recede from it. When the earliest catalogues were constructed, the present Pole star was 12° from the pole; it is now less than 14, and will approach to within 10, whou it will begin to recede and give place to others. To take longer periods: When the Great Pyramid of Ghizeh was built (nearly 4000 B.C.), by looking down its narrow entrance passage (the slope of which inclines 26° 41' to the horizon) a Draconis was seen at its lower culmination a pole star about 3" 44' from the pole. After the lapse of 12,000 years, a Lyrus, the brightest star in the northern homisphere, will be the pole star, approaching to within about 5° of the pole

The north pole of the heavens may be found thus: —Draw a line from a Uraw Majoras (the first of the three stars of the tail) to Polaris, and produce it about 1½°. It is convenient for the navigator thus to know the position of the pole with respect to Palaris. When a Uraw Majorus is six hours from the meridian (which can be estimated with sufficient exactness by the eye, or more definitely obtained from a transit table) the Pole star is at its greatest distance also from the meridian. In this position of Polaris its altitude will be nearly the same as that of the pole, which is equal to the latitude of the observer. In any other position, with the aid of tables the observed altitude of Polaris may be reduced to the meridian altitude, and thus the altitude of the pole deduced and the latitude of the observer expeditiously found. Such tables are given in the "Nautocal

Almanac," which also furnishes other useful information respecting this most important star. Mag. 2.2, 1896; R.A. 1h 21m, Dec. + 85, 45'—See Latitude.

Poles (Gk πόλος, "a pivot" on which everything turns, the axis of the sphere) The points at the extrenaties of the axis of the colestial sphere, which in the diurnal revolution appear stationary. and about which the whole of the heavens appears to turn as upon pivots. This is the primary use of the term. Hence it was extended and applied to the extremities of the axis of the earth about which it rotates; hence, also, its more purely geometrical uses. Thus the motion of every circle of the celestial sphere whose plane is perpendicular to the axis of rotation is referred to these stationary points. which are therefore generally called the "poles" of all circles, every point of which is equally distant from each of them, and in particular they are the poles of the great circle of such a parallel system. For example, we have the "poles of the equator," the "poles of the equinoctial," the "poles of the ecliptic, the "poles of the horizon," and of their several systems of parallels. The term is still further extended to physics. Thus, when it was found that the magnet was not always directed to the north pole, but to another point, this was naturally named the "magnetic pole."

Poles of the Earth.—The two points in which the axis of the earth meets the surface. They are distinguished as the North Pole and South Pole—the former being the one nearest to Europe, the latter that most remote from it. The poles of the earth are poles of the Equator.

Poles of the Heavens.—The two points of the celestal concave in which the axis of the heavens is conceived to meet its surface. The poles of the heavens are distinguished as the North Pole and

South Pole the former being that towards which the north pole of the earth is directed, the latter that towards which the south pole of the earth is directed. The axis of the earth, always remaining parallel to itself throughout her annual revolution round the sun, is considered always to be directed to the same points—the poles of the heavens; for great as the earth's orbit actually is, it vanishes relatively to the infinite distance of the celestral concave.

Pollux. -The name of the bright star β Geminorum.--See Gemini.

Position of Ship. - The position of a ship at sea is in general defined by the intersection of two determinate lines on the earth's surface, on both of which the ship is ascertained to be. Different systems of these pairs of lines give rise to various methods of determining the position of the ship. (1) A parallel of latitude and meridian are the pair of lines most systematically adopted, the latitude giving the former, the longitude the latter. (2) A parallel of latitude and a constant rhumb line were used more frequently before chronometers were constructed with sufficient perfection to furnish an easy means of finding the longitude. (3) Two lines of equal altitude furnish a very useful method of finding the ship's place. [See Summer's Method.] (4) When the ship is in eight of land, cross bearings furnish the pair of lines required. The position of the ship is always registered by its latitude and longitude.

Position, Parallels of.—A name sometimes used for "Circles of Equal Attitude," the curves giving the position of the ship in Summer's method.

These circles belong to a terrestrial system, determined, however, by a particular lieavenly body at a definite moment, giving the volce. Each curve is the locus of places whose zenith is at the same distance from this pole.

The great circle of the system is the Terminator, and (the ordinary corrections being made) this is the boundary of the hemispheres, in one of which the body is visible and in the other invisible. From any point of the terminator the body will appear in the horizon.

The pole of the terminator is the spot in whose zenith the body is situated; and this is the only place where it has an altitude of 90°.

If small circles be drawn parallel to the terminator, each will mark out all the places on the earth's surface where the body is seen at the same altitude; these are what are called Circles of Equal Altitude or Parallels of Position. Each term is appropriate from its special point of view.

A great circle secondary to the terminator will give the line of bearing of the body from any particular spot on a parallel. The "Line of Bearing" and "Line of Position" are at right angles to one another.

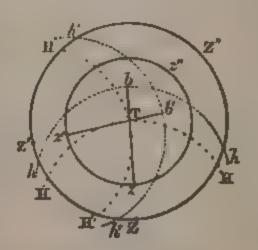

For the sake of clearness of conception, we may compare the pole of the terminator with that of the equator and with that of the horizon. The pole of the equator is a fixed point on the earth's surface, and is independent of the position of the spectator and of any heavenly body observed; the pole of the horizon simply marks the position of the spectator, and moves with him; the pole of the terminator is dependent on the heavenly body observed, and is defined by the vertical from its place to the earth's surface at any particular moment.

The two systems, of the horizon and terminator, are frequently confused, and they demand therefore some further consideration in

Connection with each other. Two points must be borne in mind:—
First, that the horizon system has properly reference to the celestial concave while the terminator system is concerned with the terrestrial aphere; secondly, having substituted for the elements of the terminator system their celestial counterparts, the two systems are properly described as complementary. The pole of one system is always on the great circle of the other; and the great circle ordinate of one is equal to the polar distance of the other.

The confusion we have referred to arises from the application to a system on the terrestrial sphere of a term "Parallels of Altitude" already appropriated to a system of the celestial concave; the two not even corresponding to each other. Parallels of Altitude are small circles of the celestial sphere parallel to the horizon; Parallels of Equal Altitude are small circles of the terrestrial sphere parallel to terminator; the term Zenith Parallels describes the counterparts of the latter on the celestial concave, and serves to connect the two conceptions.

The annexed figure may serve to illustrate the terms: The centre T is the pole of the term-inator ZZ'Z"; the horizons of all the points ZZ'Z", . . . . , viz. HTH, H'TH', . . . , passing through T. The smallcircle z'z" is the parallel 30" distant from T; the body in the zenith of T having an altitude of 60° from every point on this parallel. The line of

bearing at z is a T b, at right angles to the curve at z.

Post Meridiem (L. "after noon," abbreviated P M : -The designation of the latter twelve hours of the civil day - those, virially following the sun's passage of the meridian. The other twelve are distinguished as the hours Ante Meridiem, "before noon."

Precession of the Equinoxes.—The equinoctial points have a slow backward movement (from east to west) along the ecliptic. In consequence of this retrogression of the first point of Aries, the epoch of the equinox "precedes," or is earlier than it would otherwise have been.—See following arricle; and Equinoctial Points.

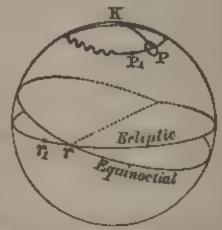

Precession and Nutation L. precessions, " a going before"; L. mitatio, "a nodding") - Corrections which reduce the place of a heavenly body to fixed and determinate celestral circles The co-ordinates, which define the position of the stars, are found to undergo continual variations, witch affect all the stars, and cannot, therefore, be referred to any "proper motions." They ares from a displacement of the planes and circles to which the bodies are The two primary planes used are the ecliptic and the equinoctial, and the origin of coordinates is determined by the line of their intersection. The ecliptic is found to be very nearly a fixed plane, its position, however, being disturbed by planetary influence, which very slightly affects the right ascensions of the stars. But the luni solar attraction on the protube and equatorial mass, forming the excess of the terrestrial spheroid above its inscribed sphere, is considerable, and it causes the line of intersection of the equinoctial and ecliptic to have a gradual retrograde motion, the first point of Anse moving backwards along the schiptic at a yearly rate of 50.38". The attractions of the planets tend to alter the plane of the earth's orbit. We may consider the combined result as increasing the longitudes of all stars by a common mean quantity 50 2" per annum, which is called

the general precession. Again, owing to the variable action of the moon, the inclination of the equinoctial to the ecliptic undergoes small periodical fluctuations about a mean value, the cycle being identical with the variations in the lumi-solar procession. These subordinate motions are named nutation.

The relative changes in the planes of the two great circles may beat be exhibited by the consequent alterations in the place of the pole of the equinoctial with reference to the pole of the ecliptic. The effect of precession is to cause the mean place of the pole of the equinoctial P, to describe a small circle, with radial arc KP equal to the obliquity, round the pole of the ecliptic K, in about 25.800 years. The effect of notation is to cause the true pole of the equinoctial to describe a small ellipse about its mean place P; with major axis 18.5° pointing to K, and minor axis 13.7°, the revolution being

completed in 18 years 220 days. The resulting true path of the pole will be a wavy curve.

In the figure 7 is the position of the first point of Aries at the beginning of any tropical year, and 7, its position at the beginning of the next, 7.7, being 50.2" measured backward, i.e in the direction opposite to the sun's motion. By this retrogression the

tropical year is shortened, and the return of the sun to the equinox takes place earlier than it would otherwise have done, hence the term precession of the equinoxes.

P and P, are the positions of the pole of the equinoctial corresponding to T and T. This explains how different stars occupy at different eras the position of polar star.

133

"Pricking the Ship off."—Marking the ship's the chart. This is always done at noon, when the accreckoning for the twenty-four hours is closed; and also when the course is shaped for the night.

Prime Vertical (L. primus, "first").—That ver which cuts the meridian at right angles. It intersects the the east and west points. The word "prime" may, per reference to the east point as being the point of reference or rising of the heavenly bodies. To a spectator on all the heavenly bodies rise perpendicularly to the horizonly those that rise at the east point which perform a greatheir diurnal course—viz. the prime vertical.

Primitive Plane.—(L. primitīvus, "the first of its s In projections the primitive plane is that on which the su represented is delineated.

Prismatic Compass.—A compass fitted with a mirror for the observation of azimuths.—See Compass.

Procyon (Gk. προκύων; from προ, "before"; κύων, so called from its rising before the Dog-star Sirius).—I name for the "lesser dog-star," a Canis Minoris.—S Minor.

Projection (L. projectio, "a throwing forward delineation of a proposed figure on a given surface, formed of lines drawn according to some definite laws. The projection of a generally conceived as made by straight lines plane. This plane is called the "Primitive Plane." A is also drawn between Natural and Artificial projection Natural Projection of a surface on a given plane is such a content of the surface of a surface on a given plane is such a content of the surface of the surfa

of it as would be formed by drawing straight lines from the eye in a definite position through every point of the surface to meet the plane, the original and the representation producing the same effect on the origin of vision. (2) An Artificial Projection is a delineation of the surface on a plane traced according to fixed laws, not being a perspective representation.

Projections of a Sphere.—Delineations of the surface of the sphere on a plane made according to definite laws, and furnishing the means of constructing maps and charts. Projections of the sphere are either Natural or Artificial,

1 Natural Projections of the sphere are defineations of the surface on a plane, defined in position, representing the sphere as it appears to the eye situated at a given point. According to the relative positions of the sphere, the eye, and the primitive or plane of projection, there are different methods of natural projection, the three most important of which are the Orthographic, Mercographic, and Central or Guomanic (a) In the Orthographic the eye is indefinitely distant from the sphere, so that the visual rays are parallel to one another, and the primitive is perpendicular to their direction; (b) in the Stereographic the eye is situated on the surface of the sphere, and the primitive passes through the centre so as to have the eye in its pole; (c) in the Central or Guomanic the eye is at the centre of the sphere, and the primitive is a tangent plane.

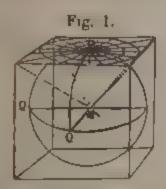

Projections of the sphere, on whichsoever of the above methods they are made, are further named Equatorial, Meritimal, or Harmontal, according as the primitive coincides with or is parallel to the equator, the meridian, or the horizon. All perspective representations of the sphere distort those parts which are not projected near

the centre of the primitive. Thus, in a map on the orthographisprojection, countries at a distance from the centre of the primitive
are unduly contracted, while the reverse is the case in maps on the
central projection. In maps or charts of small portions of the earth's
surface this is of little consequence, as the middle of the map may
always be taken for the centre of the primitive; but for extensive
tracts the distortion near the edge of the map is considerable, and
constitutes an objection.

2. Artificial Projections of the sphere are defineations of the surface on a plane traced according to fixed laws, not being perspective representations. Mercator's chart, which is that of the greatest importance to the navigator, is an artificial projection. Here the meridians are parallel straight lines equidistant from each other, the parallels of latitude are perpendicular to the meridians at such distance from each other, increasing from the equator, that the measures of a degree of longitude and latitude at any point of the projection shall have the same ratio as exists between their measures on the surface of the sphere at the corresponding point.

Projection, Central or Gnomonic (Gk. γνώμων, "the style" or index of a dial) A natural projection on a tangential plane as primitive, the eye being at the centre of the sphere. It is called the "gnomonic" projection, as being that used in the construction of the sun-dial. The designation "central" would seem to be the preferable one, as marking the characteristic feature in the manner of making the projection, and not merely embodying one of the practical applications of its principle. The most important properties of this projection are. (1) Every great circle of the sphere, since its plane passes through the eye, is projected into a straight line: 2 Every small circle of the sphere is projected into a conic section.

plane parallel to the primitive, a parabola when it touches that plane, and a hyperbola when it intersects that plane. In the case of the original circle being parallel to the primitive, its projection will be a circle concentrio with the primitive. The first property mentioned renders charts on this projection very convenient for great-circle sailing. An entire hemisphere cannot be thus represented, as the circumference which terminates it is on a level with the eye parallel to the primitive plane. I he method, however, is applicable for maps of the circumpolar regions of the earth, but as countries recede from the centre they become to a considerable degree unduly enlarged. The whole sphere is conveniently projected on the aix sides of a circumscribing cube; and the maps of the earth and of the stare, published by the Society for the Diffusion of Useful Knowledge, are drawn in this manner (fig. 1).

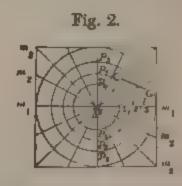

Fig. 2 represents an equatorial central projection of the terrestrial sphere: P the pole (centre of the tangential plane parallel to the equator);  $m_1m_1, m_2m_3, m_4m_5, \ldots$ , meridians;  $p_3l_4p_1, p_2l_3p_2, \ldots$ , parallels of latitude; GC an arc of a great circle

Projection, Orthographic (Gk. δρθδε "straight," "upright ';
γράφειν, " to grave").—A natural projection made by straight lines.

conceived to be infinitely distant from the sphere, so that the visual rays are parallel to one another, and a diametral plane is chosen for the primitive (fig. 1). A circle of the sphere as thus projected is an ellipse whose axis major = diameter of the circle, and axis minor = (axis major) × (cos inclination of the circle to the primitive). When the circle is parallel to the primitive, the projection is an equal circle; when it is perpendicular to the primitive, its projection is a straight line equal to the diameter. In maps and charts on this projection, regions at a distance from the centre of the primitive are unduly contracted; and hence, though very useful for small portions of the globe, it is of little service for large tracts. The orthographic projection is convenient in astronomy for the delineation of sclipses and the transits of the heavenly bodies.

I've I

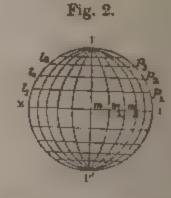

Fig. 2 represents a meridional orthographic projection of the terrestrial sphere; PMP'M, meridians—primitive plane; Pm, Pm, Pm, Pm, . . . . meridians; MM' equator;  $p_1l_1, p_2l_3, p_3l_3, \ldots$  parallels of latitude.

Projection, Stereographic (Ck. srepeds, "solid," "cubic"; producer " to grave ").—Strictly speaking, the word "stereographic"

is applicable, in a general sense, to every perspective representation of a solid on a plane; but in the case of the sphere it has a limited technical sense, being confined to one method, and distinguishing a particular projection from others, such as the "orthographic" and "central". The stereographic is a natural projection of the concavity of the sphere on a diametral plane as primitive, the eye being placed on the surface at the opposite extremity of the diameter, perpendicular to the primitive (fig. 1). Its most important properties are:

(1) All circles of the sphere are projected either into straight lines or circles; (a) those which pass through the eye into straight lines; and (b) those which do not pass through the sye into circles, being the sub-contiary sections of cones whose common vertex is the eye, and bases the circles to be projected. (2) The angle of intersection of two circles on the sphere is the same for their projections; hence

Fig. 1.

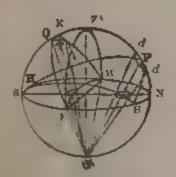

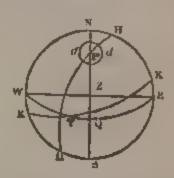

Fig 2.

also every very small triangle on the sphere is represented by a similar triangle on the projection. The first property mentioned renders the construction of maps on this projection very simple; the second shows that the meridians and parallels of latitude intersect each other at right angles as they do on the globe, and this also facilitates the construction of maps. Again, it is a consequence of the second

property that the projection preserves a general similarity to the reality in all its parts. In receding from the centre, the dimensions are somewhat unduly enlarged, but a hemisphere may be projected without any very violent distortion of the configurations on the surface from their real form,

Fig. 2 represents a horizontal stereographic projection of the celestial concave: NESW, horizon—primitive plane; Z, zenith - pole of primitive plane; NS, meridian; EW, prime vertical; EQW, equinoctial; KK ecliptic; HPH, hour circle; dd, parallel of declination.

Prolate Spheroid (L. prolatus, "prolonged").—A spheroid elongated in the direction of its axis, and distinguished from as oblate spheroid. It may be conceived to be generated by the revolution of an ellipse about its major axis.

Proportional Logarithms.—The logarithm of A (a constant quantity), diminished by the logarithm of any other number less than A, is the proportional logarithm of that number. The term, however, is often technically restricted to one particular case by the following definition —The logarithm of the number of seconds in 3h or 3°, diminished by the logarithm of the number of seconds in any period less than 3h or angle less than 3°, is called the proportional logarithm of that period or angle. Proportional logarithms are used in finding the G M.T. corresponding to a given lunar distance.—See under Logarithms.

Proportional Parts.—In logarithmic tables, small auxiliary tables are annexed called "Tables of Proportional Parts," the use of which is to facilitate the process of interpolation, thus enabling is to extend the range of our table of logarithms. Their construction

depends upon the following principle — The difference between the logarithms of two numbers not differing much from each other is proportional to the difference of the numbers, or

$$\frac{\log_{10} (N + n) - \log_{10} N}{\log_{10} (N + 10) - \log_{10} N} = \frac{n}{10}$$

The tables of proportional parts are therefore simply the results of the expression

n | log. 10 (N + 10) - log. 10 N

reduced to numbers for each value of n from 1 to 9. Example:—Our table of logarithms is calculated for 4 figures, but we want the logarithm of a number of 5 figures, 23453. Now, this lies between 23450 and 23460, which differ by 10. The difference of the mantissæ of the numbers, which are the same as those of 2345 and 2346 (viz. 370143 and 370328) is 185. The difference of the mantissa of 23450 and that of 23453 will be found from the proportion

$$10:3...185:x, \therefore x = \frac{3}{10}185 = 56$$

Hence the mantissa of 23453 is 370199. The process may be continued and the mantissa of a number consisting of 6 figures, and so on, found. The tables of proportional parts are used also in the converse problem, and the number corresponding to a mantissa lying between two tabulated ones may be determined.

Q.

q. - Of the letters used to register the state of the weather in the log-book, Q indicates " Squally."

Quadrant. (L. quadrans, "the fourth part"). - The fourth part of the circumference of a circle. It contains 90°, and subtends a right angle at the centre.

Quadrant.—An astronomical instrument, the arc of which is 90°, and which is used for measuring angular distances. The form of the instrument has varied through successive improvements, the principal advances from the Simple Quadrant being Davis' Quadrant and Hadley's Quadrant.

The word is now improperly applied to a rough reflecting sector, the arc of which is only 45°-See Octant, Sector.

Quadrature (L. quadratum, "a quartering") —The moon is said to be in quadrature when at one of the two points of her orbit equally distant from conjunction and opposition, when her position is 90° from the sun.—See Moon's Fhases.

Quicksilver Horizon.—Quicksilver is the substance best adapted to form an artificial horizon. As a fluid, its surface assumes at rest a horizontal position, and this surface has the brightness of a burnished silver mirror.—See Artificial Horizon.

R,

r.-Of the letters used to register the state of the weather in the log-book, r indicates " Rain-i.e. Continuous Rain."

Race (D. ras; Sw. resa).—When the tide-wave, while advancing along the shore, is arrested by a promontory, the water, under certain conditions, attains a height which causes it to flow off obliquely with a considerable velocity; such a current is called a "Race." Example—the Race of Portland. The word is doubtless of Scandinavian origin, the inhabitants of the Orkney Islands calling these currents roosts.

Radius of Curvature.—See Curvature.

Radius Vector (L. vector, "one that carries").—The radius which, revolving round a fixed centre or pole from an initial position, defines the place of any point in space. The length of the radius vector between the pole and the point is one of the polar co-ordinates of the point.—See Co-ordinates.

Rate of Chronometer.—The daily change in its error; designated gaining when the matrument is going too fast, and lowing when it is going too slow.—See under Chronometer.

Rating the Chronometer. -Determining its rate. -- See under Chronometer.

Rate of Sailing. This is found by "heaving the log," as a rule, every hour; but it must be borne in mind that the result which this gives may be very far from the truth for the whole hour. The rate varies with the strength and direction of the wind, the quantity of sail set, the true of the sails, the running of the sea, and the skill of the belimman. Experience and practice are requisite for truly estimating the rate. Various plans have been proposed for obtaining the rate; but the ordinary log, thrown every hour, and the patent log towed overboard for a continuous period, are those universally adopted.—See Log.

Rational Horizon (L. rationalis, from ratio, "reason," a "reckoning").—A plane passing through the earth's centre, parallel to the tangent-plane at the observer's station. It is distinguished from this plane, which is called the sensible horizon. As the zone they include is of evanescent breadth compared with the indefinite distance of the celestial concave, they coincidently out it in the same great circle—the celestial horizon.—See Horizon.

Reaumur's Thermometer.—A thermometer its inventor, in which the distance between the freezi point of water is divided into 80°, the former being multiple of the comments of t

Reciprocal Bearings.—The bearings of two each other taken simultaneously. They are used in one for determining the deviation of the standard cor students appear to have a difficulty in determining deviation deduced is easterly or westerly. The following treatment will remove all uncertainty. Let I) and V b of the ship and shore compasses; the line joining From this initial line lay off the two angles at D an give the direction of the two needles. Through V draw a line parallel to the needle at D; if this lies to the right of the needle at V the deviation is easterly, if to the left it is westerly. Example—the shore compass bears from the ship N. 38° W., and the ship compass bears from the shore S. 46° E. At D the needle lies 38° to the east of the fixed line DV, and gives Nc DSc the direction of the needle affected by deviation. Again, at V the needle lies 46° to the west of the fixed line VD, and gives Now VSm the direction of the needle unaffected by deviation. Through V draw N to No DSc. It will now be seen at once that the being drawn to the west of the magnetic north, the d compass is westerly.

Reckoning (A.-Sax. recus, Ger. reckses).—I finding the position of a ship by observations and oak

is said to be out of her reckoning when the position so determined turns out to be different from the true place. Dead reckoning describes the method where the data used are derived only from the use of the log and compass.

Reduced Latitude.—The "central," "geocentric," or "latitude on the sphere" is so called. Except at the poles and the equator it is always less than the normal, true, or latitude on the spheroid, and the correction for finding it from the latter (which is that deduced from observation) is subtractive; hence the name. The reduced latitude is the angle which the line joining the station of the observer with the centre of the earth makes with the plane of the equator.—See under Latitude.

Reduced Zenith.—The point in which the line joining the centre of the earth and the observer's station produced into space meets the celestial concave. Except at the equator and the poles, the reduced is lower in position than the true centh; hence the name.—See Zenith.

Reduction — The process of applying the corrections to the apparent place of a heavenly body to obtain its true place. These corrections are five in number. (1) Refraction allows for the bending of the visual rays from a straight course in the passage through the atmosphere, and does away with the disturbance of this medium; (2) Parallax places the observer virtually at the centre of the earth instead of on its surface; (3) Aberration gives what the observation would have been from a motionless instead of a moving station; (4 and (5) Procession and Nutation refer the place of the body to fixed and determinate instead of constantly varying celestial circles.

Reduction of the Latitude, or "Angle of the Vertical".—
The correction by which the latitude on the spheroid is reduced to
the latitude on the sphere, which is often required in the solution of
problems.—See under Latitude.

Reduction to the Meridian.—The latitude of a place is most simply determined by the observation of the meridian altitude of a known heavenly body. When such an observation cannot be obtained by reason of the state of the weather, the altitude of the body may often be obtained a little before or a little after its meridian passage. And if at the time of observing such an altitude near the meridian the hour-angle of the body is obtained, we may find by computation very nearly the difference of altitude which to reduce the observed to the meridian altitude. correction is called the "Reduction to the Meridian." In point of simplicity, this method of finding the latitude is next to that by the actual observation of the meridian altitude. Even when the meridian altitude can be observed, it will be liable to errors of observation, and may be too great or too small. A reduction to the meridan which will enable us to make use of a larger number of observations will obviously diminish the probable error of each. - See under Latitude (II.).

Reflecting Circle.—An astronomical instrument for measuring angular distances; it is the same in principle with the sextant, but its limb is a complete circle.—See under Circle.

Reflecting Sector.—The general name for all instruments similar in principle to Hadley's Quadrant, whatever be the extent of their limb.

Reflection (L. reflectère, "to turn back"),—A turning back after striking upon any surface, applied to light, heat, sound, etc. We are concerned only with light. When a ray of light is incident upon a plane polished surface, the angle which its direction makes with the normal (or perpendicular) to the surface is called the angle of incidence, and the angle which its direction, after being turned back from the surface, makes with the normal is called the angle of reflection. The experimental laws of reflection are—(1) The incident and reflected rays he in the same plane with the normal at the point of incidence, and on opposite sides of it; (2) The angles of incidence and reflection are equal. Three most important deductions from these laws (being practically applied in the construction of instruments) are the following:—

1. Principle of the Artificial Horizon.—The image of an object reflected from a horizontal surface appears as much below the horizontal line as the object itself is above it; and hence the angular distance between the object itself

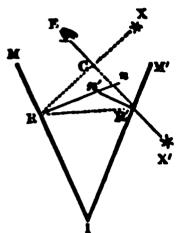

i. 15) . . XNX = 2HNX.

and the reflected image gives double the

altitude of the object. For the angle of incidence (XNM) being equal
to the angle of reflection (MNE), LHNX = LRNE = LHNX'(Enc.

2 Principle of Hadley's Sextant, and similar instruments.—The deviation of a ray of light which is reflected at the surface of two plane mirrors, inclined to each other at a given angle, in the plane perpendicular to the line of their intersection, is double the angle between the mirrors. Let IM, IM' be sections of the two mirrors by the plane in which the course of the ray XRR E lies, and let XR and R'E intersect each other in C. To an eye at E the image of the

source of light X will appear in the direction ER', the ray having

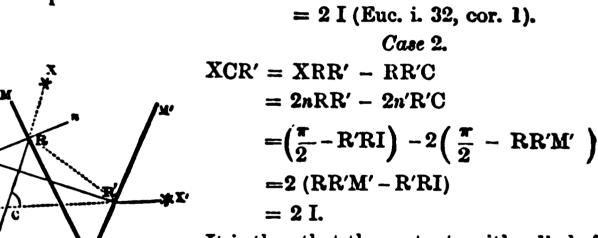

been deflected through the angle XCR'. To find this angle. There are two cases, according at the normals Rn, R'n' intersect (in the point a) between the mirrors or not.

Case 1.

= 2 (nRR' + n'R'R)

 $= 2 (\pi - Rn'R')$ 

XCR' = CRR' + CR'R

It is thus that the sextant, with a limb of 60° only, can be used to measure an angle of 120°.

The divisions on the limb are graduated at double their actual value, so that the reading-off gives at once the angle observed.

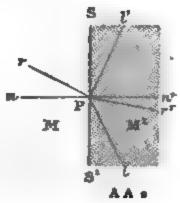

3. Principle of the Prism Reflector.—When a ray of light attempts to pass from a denser into a rarer medium, and the angle of incidence exceeds a certain magnitude, depending upon the two media, it will not pass through, but is reflected back into the denser medium.—See under Refraction.

This fact enables us to utilize a prism (say of crown glass) to change the direction of a pencil of light by which an object is seen, making its apparent place, as viewed through the prism, coincide with

the actual place of another object viewed directly. Thus a prism carried on a ring parallel to, and concentric with, the compass card is the means used for reading off by reflection the graduation of the eard below it, while the object whose azimuth is being observed is viewed directly. Such is the arrangement in the old Azimuth Prismatic Compass. In the same manner the prism attached to Lord Kelvin's Compass furnishes the means for reading the graduation by reflection while viewing the object directly, or viewing the object by reflection while reading off the graduation directly.—See Compass, Aximuth.

Refraction (L. refractus, from refringere, "to break").—When a ray of light passes obliquely from one medium to another of different density, its direction is broken and changed at the surface which separates the two; this change of direction is called refraction. The following are the experimental laws of refraction; (1) The incident and refracted rays lie in the same plane with the normal (or perpendicular) to the surface at the point of incidence, and on opposite sides of it; (2) The angle of incidence and the angle of refraction being those which the ray makes with the normal, the sine of the angle of incidence bears to the sine of the angle of refraction a ratio dependent only on the nature of the media between which the refraction takes place, and on the nature of the light.

Let SPS<sup>1</sup> be the common surface separating the two media M and M<sup>1</sup>, of which M is rarer than M<sup>1</sup>; and let the angle of incidence  $\pi Pr$  of the ray passing from M to M<sup>1</sup> be called  $\phi$  and the angle of refraction  $\pi Pr'$  be called  $\phi'$ . Then Sin  $\phi = \mu$  Sin  $\phi'$ , where  $\mu$  is a quantity independent of  $\phi$  and depending only upon the relative densities of M and M<sup>1</sup> and the nature

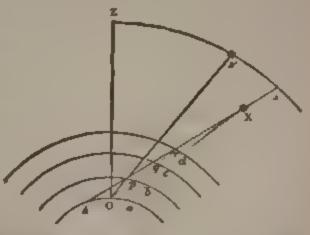

of the light. Thus it has a certain value for refraction from vacuum into plate glass, another from air into water; it also has one value for red and another for green light. The quantity  $\mu$  is called the refractive index, and when only one medium is mentioned it is understood to indicate the refractive power of that substance can ray entering it from vacuum. Thus for the diamond  $\mu=2.459$ , for ice  $\mu=1.509$ . Experiment shews that when the ray is refracted from vacuum into any known medium  $\mu$  is greater than unity, and so generally when it takes place from a rarer to a denser medium: is other words, the refracted ray lies nearer to the normal. The converse is the case when the ray passes from the denser into the rarer medium. For no known substance is the index of refractive greater than 3, so that  $\mu$  varies from 1 to 3.

When a ray passes from the denser to the rarer medium, it is refracted further from the normal; and as  $\sin \phi = \mu \sin \phi$ ,  nd varies from  $\frac{1}{3}$  to 1. If now the angle  $\phi$  is increased, the angle  $\phi$  is also increased, and the latter becomes a right angle when the former is equal to the angle whose sine is equal to  $\mu$  or  $\frac{1}{\mu}$ . Hence when the ray from the denser medium strikes the separating surface at an angle whose sine is  $\frac{1}{\mu}$  it is refracted along the surface and does not emerge. If  $\phi$  is further increased, the ray of light ( $\ell P\ell^1$ ) is reflected back into the denser medium according to the laws of reflection. For example:—The refractive power of crown glass varies from 1.525 to 1.554; taking it at  $\frac{3}{2}$ , reflection occurs when  $\phi$  exceed  $\sin^{-1}\frac{2}{3}$ , which is 41.4. This is the principle of the prism reflectors attached to aximuth compasses.—See Compasses, Aximuth.

The subject of refraction is of great importance to the navigator being the principle on which the telescopes used by him are matructed, and as affecting the observations made by him.

Refraction, Astronomical.—The deflection caused in a ray of light from a heavenly body by its passing through the earth's atmosphere; and (as an object always appears in the direction that the risual ray has when it enters the eye) the consequent alteration in the apparent place of the body as seen by a spectator on the earth's arface. The term Refraction is also used in a technical sense for the correction to be applied to the place of a heavenly body, as oftnally viewed through the atmosphere, to reduce it to what it would have been had the body been viewed through a uniform addium. The general effect of refraction is to cause the heavenly bodies to appear higher above the horizon than they actually are.

tet O be the station of as observer on the arth's surface, OZ the ormal to the surface at 1. Z the true zenith. The atmosphere may be enceived as formed of enceutric stra's of air, minishing in density as acy recede from the arth's surface Let X be

heavenly body beyond the limit of the atmosphere. Then, if there are no atmosphere, X would be referred to x on the celestial converted by means of a ray of light proceeding in the straight line XO; at the intervention of the atmosphere causes this ray to be as

refracted that it never reaches the eye of the observer at O at all, ice on entering each stratum it is bent towards the normal [and more of as these strata increase in density), and finally reaches the earth surface at a. The observer at O actually sees the body X by a my which, if there were no atmosphere, would strike the earth's surface behind him at k, but which, by the intervention of the atmosphere is refracted in the direction rqpO. In the limit, when we consider the strata to be indefinitely thin, the path of the ray through the atmosphere will be a continuous curve, and the direction in which the object will be seen will be the tangent to the curve at the pour nearest to the observer's eye. As the atmosphere is similar of opposite sides of the vertical plane through ZOX, the rays of light from X will not be refracted out of that plane; hence a heaventy body appears to be raised by refraction in a vertical plane above its The body X will thus be referred by the observer at 0 true place. to the point x' of the celestial concave. The arc xx' is therefore the alteration in the apparent place of the body X due to refraction, and this quantity has to be applied as a corretion to the apparent place in finding the true. As refraction, like parallax, takes place in a vertical plane, these two corrections, though altogether different in the character, are combined, and form the "Correction in Altitude"

Refraction is of all astronomical corrections the most difficult to determine with accuracy. The refracting power of the atmospher varies with its density, and this is affected in any particular stratum not only by the superincumbent pressure, but also by its i imperature and its degree of moisture; and we are not definitely acquainted with the laws of their distribution. The following are the general feature of astronomical refraction.—

1. It takes place in a vertical plane. In the zenith there is no refraction; in descending from the zenith to the horizon it continual

increases; the rate of its increase, especially near the zenith, is nearly in proportion to the tangent of the apparent zenith distance; the law, however, near the horizon becoming more complicated. The average amount of refraction for an object at the apparent altitude of 45° is about 1' (more accurately 57"); at the visible horizon it amounts to 33', which is rather more than the greatest apparent diameter of the sun or moon. We must here note some resulting phenomena.

- (a) When the bodies are near the horizon the effect of refraction will be different in degree for different points of so considerable a disc as that of the sun or moon. The highest and lowest points of the vertical diameter will both be raised by refraction, but the lowest more than the highest; consequently the diameter will be shortened, and the same thing will be true for every line parallel to this diameter. The horizontal diameter will not appreciably be altered. There will in reality be a slight, though a very slight alteration, as the two extremities of the diameter will be raised in vertical arcs which meet in the zenith. From the above it appears that when observations of the sun or moon are taken near the horizon, a correction must be made to the semidiameter before applying it.
- (b) Since the refraction near the horizon amounts to more than 33', the sun will appear just above the horizon when he is in reality entirely below it; and hence refraction has a considerable effect, especially in high latitudes, in lengthening the period of daylight. It has a similar effect in the time of the rising and setting of the other heavenly bodies.

- (c) Hence also the great refraction at the horizon sensibly affects the apparent amplitude, and a correction for refraction thus becomes necessary in obtaining correctly the true amplitude of a body.
- 2. When the barometer is higher than its mean height, the amount of refraction is greater than its mean amount; when lower, less The colder the air, the greater the refraction. The Tables of Refraction in use among navigators are constructed on the supposition that at the level of the sea the barometer stands at 30 inches and Fahrenheit's thermometer at 50°, according to Ivory. The argument of the principal table which gives this mean value, is the apparent altitude; the corrections for the height of the lurometer and thermometer being given in auxiliary tables.

Refraction, Terrestrial.— The change in the position of terrestrial objects due to their being viewed through the medium of the atmosphere. In astronomical refraction the object is without the limits of the atmosphere; in terrestrial refraction the object is within the atmosphere. The effect is in general to make an object appear higher than its true place, and its average amount is about to find intercepted arc. As a minute of a degree of a great circle of the earth is in length nearly a mile, the refraction in minutes may be thus obtained from the distance in miles. The amount, however, of terrestrial refraction is subject to great irregularity, and varies between the and the first the intercepted arc. The most important object to the navigator which is thus affected is the sea horizon. In consequence of refraction, the apparent dip is less than the true.—See under Depression.

Regulus (L. diminutive of rer, "a king") —The name of the bright star a Leonia. The word is a translation of the old Greek name for the star parallexes, "the little king."—See Leo.

Repeating Circle. An astronomical circle constructed on the principle of repeating the measurement of the angle required without multiplying the single reading off, thus theoretically diminishing by division the error arising from imperfect graduation.—See under Circle.

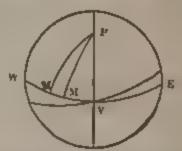

Retard or Age of the Tide.—The interval between the transit of the moon a which a tide originates and the appearance of the tide itself. See under Tide.

Retardation (L. retardatio, "a slowing" from tardus "slow").

A relative decrease in velocity, opposed to acceleration; it may be regarded as acceleration reckoned negatively.—See Acceleration.

Retardation of Mean Solar on Sidereal Time.—The change of the mean sun's right ascension in a sidereal day in

consequence of which he appears to hang back, as it were, in his diurnal revolution. Hence the name. To explain this—Let V be the first point of Aries on the meridian on any particular day, and VPM the corresponding mean solar time. When the first

point of Aries comes again to the meridian after the lapse of a sidereal day, the mean sun will have moved to the eastward by reason of his proper motion in right ascension, through the arc MM'say. Thus in the diurnal revolution from east to west the mean sun will be at M'instead of at M, appearing therefore to hang back, while the mean solar time is "retarded" with reference to sidereal time. The amount of retardation for any given interval of sidereal time will enable us to deduce the mean solar time. In the "Nautical Almanae,"

pp. 506, 507, is given a "Table for converting Intervals of Siderest Time into Equivalent Intervals of Mean Solar Time."—See Acceleration of Sidereal on Mean Solar Time.

Retrograde Motion The gradual advance of the planets in the heavens is in general from west to east. This is called the direct motion, and predominates, though broken by poriods where the planet is stationary, and periods of motion from east to west. This latter is called retrograde motion.

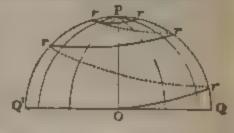

Revolving Storms. The name commonly given to those violent storms which, while advancing bodily in a definite direction, rotate about an axis with great rapidity. A more correct and appropriate generic term would be Spiral Storms. They are experienced at certain periods of the year in low latitudes, and are called, in different parts of the world, Cyclones, Hurricanes, Typhoons, and Tormados.—See Storms.

### Revolution and Rotation. -See Rotation.

Rhumb Line or Rhomb Line (Gk. péußor, Attic form of phußor, "a wharl" from phußen, "to turn round and round").—The curve on the earth's surface which cuts ail the meridians at the same angle. The word rhumb was formerly applied to the oblique points of the compass, and hence "to sail on a rhumb" was to sail on a particular compass direction obliquely to the meridian; hence again the term came to be applied to the track described by a slup which always keeps such a constant course. As the meridians all converge to the pole, any rhumb curve (making a constant oblique angle with them if continued will wind round the globe and approximate to the pole without, however, ever reaching it. That such a curve may be drawn through any two given points will appear from this consideration—

that from one of the points an indefinite number of these curves can be drawn making different angles with the meridian, and on some one of these the second point must be. It is evident, also, that only one of these curves can pass through the two points. The initial limiting direction of all the rhumb curves that can be drawn is the meridian, and the terminal limiting direction is the equator or one of its parallels, which are all at right angles to the meridian. These limits, which are circles, are properly excluded from the definition of the word "rhumb," which means oblique or slanting. The rhumb curve

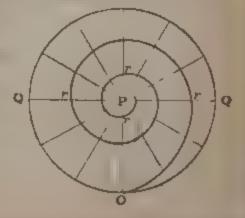

does not form the boundary of a figure like the circumferance of a circle, but is what is called a spiral. The annexed diagrams show a rhumb curve Orr starting from the equator at  $O_r$  and approaching asymptotically the north

pole P. The second figure is a projection on the equator.

The rhumb is the track used ordinarily in navigation, for although it has the disadvantage of not being the shortest distance between

two places, it possesses the advantages of not requiring the navigator to alter his course, and of being represented by a straight line on the Mercator's chart. This straight line, however, it must be borne in mind, only marks the course, equal parts of it not representing equal distances on the earth.

The Rhumb curve belongs to the class of Loxodromic Cu is an Equiangular Spiral, which see.

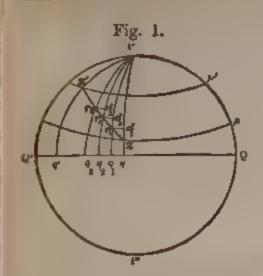

Rhumb Sailing; The Fundamental Defini
The six fundamental definitions of Rhumb Sailing may
grouped—(1) The Course and The Distance; (2) The Distance;
Longitude and The True Disference of Latitude; (3) The I
and The Meridional Disference of Latitude. These will
defined under their several heads, but they may be conexplained together with the aid of the adjoined figures. I
stereographic projection on the first meridian, fig. 2 a stere
projection on the equator, and fig. 3 Mercator's projection.
be the poles of the earth, QqQ' the equator, PQP' the first is
and let ZZ' be two places on the surface, PZq and P2
meridians, cutting the equator in q and q'. Then

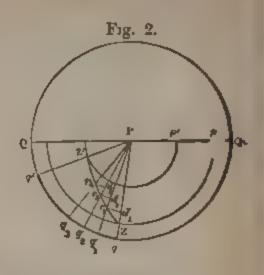

#### 1. Course and Distance.

Let the rhumb line ZZ' be drawn between Z and Z'. The c istic property of this curve is that it cuts all the intermeridians,  $Pr_1q_1$ ,  $Pr_2q_2$ ,  $Pr_3q_4$ , . . . . at the same angle, i.e. the angle  $PZZ' = Pr_1Z' = Pr_2Z' = \dots$ ; the common as is called the Course between Z and Z'; and the arc ZZ', exp nautical miles, is called the Distance.

## 2. Difference of Longitude and True Difference of Latits

Draw the parallels of latitude pZ and p'Z' through Z and 2 Qq and Qq' are the longitudes respectively of Z and Z', and their latitudes. Then the arc qq' is called the Difference of L and the arc pp' the True Difference of Latitude, of Z and Z'. It is the algebraic difference that is always meant in such case

## 3. Departure and Meridional Difference of Latitude.

On the curve ZZ' take the points  $r_1, r_2, r_3, \ldots$  indefinitely

Fig. 3.

near to each other,  $r_1$  being indefinitely near to Z, and through them draw the meridians Pq,  $Pq_1$ ,  $Pq_2$ ,  $Pq_3$ , . . . . and the arcs of parallels of latitude  $r_1d_1$ ,  $r_2d_3$ ,  $r_3d_4$ , . . . In the limit, the triangles  $Zr_1d_1$ ,  $r_1r_2d_2$ ,  $r_3r_3d_3$ , . . . in figs. 1 and 2 may be considered right-angled plane triangles; the sum of all the arcs  $d_1r_1$ ,  $d_2r_3$ ,  $d_3r_4$ , . . . between Z

and Z' is called the *Departure*; if these elementary arcs of the departure,  $d_1r_1, d_2r_2, d_3r_4, \ldots$  be supposed to become equal respectively to the corresponding differences of longitude  $qq_1, q_1q_2, q_2q_3, \ldots$  in fig. 3, the triangles  $Zr_1d_1, r_1r_2d_4, r_2r_3d_4, \ldots$  remaining similar to themselves during the change, then the sum of all the elementary portions of latitude  $Zd_1, r_1d_2, r_3d_3, \ldots$  thus increased is called the Meridianal Difference of Latitude.

But here it must always be remembered that the elements departure and meridional difference of latitude are characteristic respectively of Plane sailing and Mercator sailing; the former being found only in plane sailing formulæ, the latter only in the Mercator formula: they never appear together in the same expression.

Sailing: Fundamental Propositions.—The Rhumb three general formulæ which embody the fundamental propositions of rhumb sailing are—

1. Sin course 
$$=\frac{\text{dep.}}{\text{dist.}}$$

2. 
$$\cos \operatorname{course} = \frac{\operatorname{true \ diff.} \ \operatorname{lat.}}{\operatorname{dist.}}$$

Plane Sailing.

2. 
$$\cos \operatorname{course} = \frac{\operatorname{true \, diff. \, lat.}}{\operatorname{dist.}}$$
3.  $\operatorname{Tan \, course} = \frac{\operatorname{dep.}}{\operatorname{True \, diff. \, lat.}}$ 

3'. Tan course =  $\frac{\text{diff. long.}}{\text{mer. diff. lat.}}$  ... Mercator Sailing.

In the particular case of "parallel sailing" the formula used is

4. Dist. = diff. long.  $\times$  cos lat.

from which again the formula for the approximate method of "middlelatitude sailing" is deduced - viz.

5. Dep. (nearly) = diff. long.  $\times$  cos mid. lat.

And hence

3". Tan course = 
$$\frac{\text{diff. long.} \times \cos \text{ mid. lat.}}{\text{true diff. lat.}}$$
 (Approximately.)

Equations 4, 5, and 3" will be found proved under the headings Parallel Sailing and Middle-Latitude Sailing; the general ones 1, 2, 3, 3' may be proved together as follows:—Using the figs. l and 2 of the last article, and remembering that in the limit the triangles  $Zd_1r_1$ ,  $r_1d_2r_2$ ,  $r_2d_3r_3$ , ... are considered right-angled plane triangles; then

1. 
$$d_1r_1 = Zr_1 \sin d_1 Zr_1$$
  
 $d_2r_2 = r_1r_2 \sin d_2r_1r_2$   
 $d_3r_3 = r_2r_3 \sin d_3r_2r_3$ 

 $\therefore d_1r_1 + d_2r_2 + d_3r_3 + \ldots = (Zr_1 + r_1r_2 + r_2r_3 + \ldots) \sin PZZ'$ or Departure = distance × sin course.

2. 
$$Zd_1 = Zr_1 \cos d_1 Zr_1$$
  
 $r_1d_2 = r_1r_2 \cos d_2r_1r_2$   
 $r_2d_3 = r_2r_3 \cos d_3r_2r_3$ 

 $\therefore Zd_1 + r_1d_2 + r_2d_3 + \ldots = (Zr_1 + r_1r_2 + r_2r_3 + \ldots)\cos PZZ'$ or True difference latitude = distance × cos course.

3. 
$$d_1r_1 = Zd_1 \tan d_1 Zr_1$$
  
 $d_2r_2 = r_1d_2 \tan d_2 r_1 r_2$   
 $d_3r_3 = r_2d_3 \tan d_3 r_2 r_3$   
... = ...

 $\therefore d_1r_1 + d_2r_2 + d_3r_3 + \ldots = (Zd_1 + r_1d_2 + r_2d_3 + \ldots) \text{ tan PZZ}^r$ or Departure = distance × ton course

3'. Since 
$$\frac{d_1r_1}{Zd_1} = \frac{qq_1}{pp_1}$$
,  $\frac{d_2r_2}{r_1d_2} = \frac{q_1q_2}{p_1p_2}$ , ... (Fig 3).

 $\therefore qq_1 + q_1q_2 + q_2q_3 + \ldots = (pp_1 + p_1p_2 + p_2p_3 + \ldots)$  tan PZZ or Difference of longitude = meridional diff. lat.  $\times$  tan course.

Aid to Memory.—The above important formulæ may be easily remembered by carrying in the mind's eye two similar right angled

triangles CDP, CMQ of sensible magnitude but similar to the small evanescent triangles in Figs. 1 and 3 (Page 397). The first CDP is for Plane sailing, the second CMQ for Mercator sailing. The only element common to the two is the course C. The hypothenense CP of the plane sailing triangle represents the distance, which is not represented in any

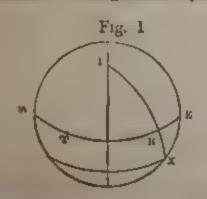

way in the Mercator triangle. The other pair of sides express the relation of Mercator to Plane sailing

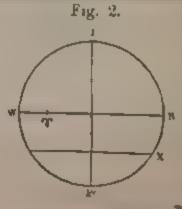

$$\frac{CM}{MQ} = \frac{CD}{DP}$$
;  $\frac{Mer. diff. lat.}{Diff. long.} = \frac{True diff. lat.}{Dep.}$ 

Rigel.—The Arabic name for the bright star β Orionis.—See Orion.

Right Ascension (L. rectus, "right," "straight"; ascensio, "rising").—The right ascension of a heavenly body is the arc of the equinoctial intercepted between the first point of Aries and the circle of declination passing through the place of the body. Or it may be defined as the angle at the pole of the heavens, between the hour-circle passing through the first point of Aries and that passing through the place of the body. Right ascension is always reckoned from the first point of Aries eastward (in conformity with the direct motions of the heavenly bodies). It is estimated either in time, by hours, minutes, and seconds, from 0 to 24h 0m 0s. or in angular magnitude, by degrees, minutes, and seconds, from 0 to 360° 0′ 0″. Right ascension and declination are the equinoctial co-ordinates for defining the positions of points on the celestial concave, and indicating their

positions relatively to each other. To understand the derivation of the term, it must be borne in mind that the words "ascension" and "descension" were formerly used with reference to the rising an ! setting of the heavenly holes. The ascension was the are of the equinocial intercepted between the first point of Aries and the east point when the body is rising; the descension the arc of the equinoctial intercepted between the first point of Aries and the west point when the body is setting. We follow further the former term only. On the oblique aphere the ascension was qualified as the "oblique ascension to a cobserver anywhere except on the equator or at the poles, the heavenly bodies shooting up obliquely from the horizon. On the right sphere the word was qualified as the "right ascension" to an observer at the equator, the heavenly bodies shooting up perpendicularly to the horizon. Thus, if X be a body rising, E the cast point, and T the first point of Aries, then (fig. 1) I E is the oblique ascension of X. Again (fig. 2) where R is the east point, 7 R is the right ascension of X. The oblique and right ascension are connected thus : - Draw (fig. 1) the hour-circle PX, intersecting the equinoctial in D; then the right ascension T K is found by taking from the oblique ascension TE the are RE, which is called the "ascensional difference," its magnitude depending upon the latitude of the observer.

Right Ascension, Circles of. - Great circles of the colesial concave passing through the poles of the equinoctial, and so called because they severally mark out all points that have the same "right ascension." In the polar system of equinoctial co ordinates, used for indicating the places of celestral objects relatively to the position of the observer on the earth's surface, these circles are named. "Hour Circles," as marking out all the points that have the same hour angle. They are generally called "Circles of Declaration," after the analogy of rectilinear co-ordinates, from the element that a measured, not by them, but upon them -the declination.—Compare "Circles of Longitude"; "Circles of Azimuth."

Right Ascension and Declination.—The equinoctal co-ordinates for defining the position of points of the celestial concars, and indicating their positions relatively to each other. Right ascension is increased on the equinoctial from the first point of Area eastward (in conformity with the direct movements of the heavenly bodies) from 0 to 24h; declination is measured on the secondaries of the equinoctial (which are hence called circles of declination) to the north and south poles of the heavens, from 0° to 90°.

Right Sphere.—The sphere in that position in which the circles apparently described by the heavenly bodies in their diamed revolution are at right angles to the horizon. This is the appearance to a spectator on the equator. The right sphere is distinguished from the parallel sphere and the oblique sphere.

Rising and Setting. - A heavenly body is said to be on the point of Rising when its centre is in the eastern part of the celestal horizon; and on the point of Setting when its centre is in the western part of the celestal horizon.

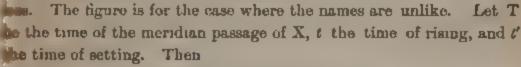

2:

To find the time of the rising and setting of a heavenly body. Let end I be the co-latitude and latitude of the observer, p and d the

olar distance and declination of the body X, and H its hour angle at rising or setting. Then in the quadrantal triangle PZX

Sin 
$$(6^n \text{ H}) = -\tan (90^n - c) \tan (90^n - p)$$
  
Cos  $\text{H} = \pm \tan l \tan d$ .

If the latitude and declination have like names, I will be greater than 6, if unlike, it will be

$$t = T - H$$
, and  $t' = T + H$ .

the time of the apparent rising and setting differs from the above by teason of the horizon parallax and refraction. The elevation of the pectator again affects the observed time of rising and setting.

Rotation (L. rota, "a wheel"), and Revolution (L. revolvere, to roll over again").—These two similar terms, though frequently sed indiscriminately, have a slightly different meaning and might with advantage be restricted in their application. We propose to confine the term rotation to indicate turning round on an axis, and the term revolution to indicate performing a periodic orbit.

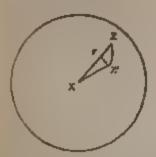

Run.—The run of a ship is the distance sailed. To run down coast is to sail along parallel to it. To run down a port was a term combing a method of making the destination in common use before longitude could be determined as easily and accurately as at resent; the ship having attained the latitude required ran along parallel, east or west as necessary.

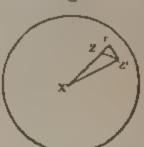

Run, Correction for; or, Reduction of an Altitude to another Place of Observation .- In "double altitudes." taken at different times, the ship may have moved in the interval between the two observations. In this case, therefore, before using the two altitudes in combination, it is, in general, necessary to apply to the first altitude the "Correction for the Run of the Ship, so as to reduce it to what it would have been had it been taken at the place of the second observation, the results of the problem under solution being sought for the later date. In celo-navigation, unstead of regarding the place of the ship on the surface of the sea, we consider her zenith, a point of the celestial concave. Let X be the place of the heavenly body at the first observation, Z the zemth of the shipat that time, and Z' her zenith at the time of the second observation. Then, had the ship's zenith been Z at the time of the first obsvervation, the zenith distance of X, instead of being XZ, would have been XZ'. With centre X and radius XZ' describe an are cutting XZ (fig. 1), or XZ produced, (fig. 2) in r; then it is evident that Z is the correction required, as applied to the zenith distance, subtractive when the ship's run has been towards the body, additive when the ship's run has been away from the body; as applied to the altitude, the converse being the case. Now, since the triangle ZZr is very small, it may, for practical purposes, be considered a right-angled plane triangle, and

#### $Zr = ZZ' \cos Z'Zr$ .

When the run of the ship has been towards the place of the body (fig. 1), the angle Z'Zr is the difference between her course and the true bearing of the body at the first observation; when the run of the ship has been away from the place of the body (fig. 2), the angle Z'Zr is the supplement of this difference. This correction may be

conveniently found by the aid of the traverse table by entering with Fig. 1. Fig. 2.

the distance run ZZ' as distance, and the angle Z'Zr as course, the corresponding diff. lat, being the correction required, additive or aubtractive as the case may be. If we define the angle between the direction of the ship's run and the bearing of the body at the first observation to be the "angle of run," the two cases are included in the formula

Correction for run = distance run × cosine angle of run.

For, when the angle of run is less than 90°, its cosine is positive, and the correction therefore additive to the altitude; and when the angle of run is greater than 90°, its cosine is negative, and the correction is therefore subtractive. If the ship does not preserve the same course in the interval, the course made good must be employed; and as it is the difference only of azimuth that enters into this question, the variation (supposed the same at both observations) is not considered; but, if the ship's course changes, the local deviation, when large, should be attended to.

S

s. -Of the letters used to register the state of the weather in the logbook, B indicates "Snow."

Sag.—To hang down on one side, to droop. To sag to leaver means that a ship is making considerable leeway, not bearing up wall to windward or holding a good wind.

Sagittarius, Constellation of (L. "The Archer"). --The ninth constellation of the zodiae, lying between Scorpio and Capricornus. It contains no star above the third magnitude.

Sagittarius, Sign of —The much division of the celeptic, including from 240° to 270° of longitude. Owing to the precession of the equinoxes, the constellation Sagittarius no longer occupies the constellation Scorpio having taken its place. The sun is in Sagittarius from about November 23rd to about December 22nd. Symbol 1.

Sailing Directions.—Books containing local information respecting various seas and constsuseful for the purpose of navigation. The chief topics are, an account of the winds, currents, tides, with directions how to take advantage of these in making certain passages, notices of dangers, such as rocks and shoals, with directions how to avoid them; descriptions of anchorages and ports, with the appearance and bearings of landmarks for making them; the particular respecting the lighthouses on the coast; memoranda of watering places, etc. Extracts from different voyages and travels are inserted, conveying in addition, much useful information respecting the physical aspect of the shores, climate, and natural phonomena, the manner and customs of the inhabitants, the productions and activities of merchandise.

Satellites (L. satelles, "an attendant"). -Subordinate bodies which revolve about some of the planets, attending upon them in their revolutions round the sun. The two groups are sometimes distin-

guished as "Primary Planets" and "Secondary Planets." Satellites generally are also called "Moons," though this is the proposition of the satellite of our globe. They are bodies of the same nature as the planets themselves, and their motions are governed by the same general laws. The earth has one satellite; Mars two; Jupiter four; Saturn eight: Uranus from four to eight; and Neptune certainly one, and probably two or more. Of these the most important to us are the Moon and Jupiter's satellites.

Saturn (named after the mythical father of Jupiter, etc.)—The planet revolving next in order to Jupiter, being about 9½ times the earth's distance from the sun; its actual diameter is about 10 times that of the earth. Besides being attended by eight distinct saterlites it has the curious appendage of a series of broad, that, rings which encircle its equatorial regions, and are probably composed of an innumerable number of small satellites; the inner one is at an interval of about half the radius of the planet. The apparent diameter of Saturn, at its mean distance from the earth, is about 13; and it is a very useful body in the problems of celo-navigation. Symbol ½.

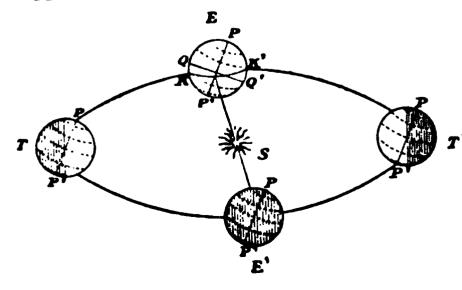

Scorpio, Constellation of (Gk. σκορπιών; L. κε νη 10, "The Scorpion").—The eighth constellation of the zodiae, lying between Labra and Sagittarius. When Scorpio rises Orion sets; a phenomenon embodied in the myth that Orion perished by the sting of a scorpion. The principal star, a Scorpii (called also Antarce), may be found by joining Spica with the South Balance (a Librar, and continuing the line to about the same distance. a Scorpii, mag. 1 1; 1896, R.A. 16h 23m, Dec.—26° 12′. β<sup>3</sup> Scorpii, mag. 2.9 , 1896, R.A. 15h 50m, Dec.—19° 31.

Scorpio, Sign of.—The eighth division of the ecliptic, including from 210° to 240° of longitude. Owing to the precession of the equinoxes, the constellation Scorpio no longer occupies the sign of this name, the constellation Libra having taken its place. The sun is in Scorpio from about October 23rd to about November 22nd. Symbol m.

Sea-Breeze.—A breeze setting from the sea towards the land. Sea-Horizon.—The small circle which bounds the portion of the surface visible to a spectator in the open sea.

Sea, Mean Level of.—The place midway between the levels of high and low water.

Seasons (Fr. saison).—The four cardinal divisions of the year—Spring, Summer, Autumn, Winter. Their succession is caused by the axis of the earth's rotation (which always remains parallel to itself) being inclined to the plane of her orbit round the sun. The elliptic form of the earth's orbit (causing her to vary her distance from the sun) has but little effect in producing the variation of temperature which distinguishes the different seasons, the temperature of any part of the earth's surface depending mainly on the exposure to the sun's rays. In our hemisphere the effect of the change of distance, if appreciable, would be to diminish the effect caused by the inclination.

Whenever the sun is above the horizon at any place, that place is receiving heat, and when below, it is parting with heat by radiation, the equilibrium of heat throughout the year

being preserved. Now, owing to the inclination of the earth's axis to the plane of her orbit, the time the sun remains above the horizon at any given place varies. To illustrate this: Let S be the sun, ETE'T' the earth in her orbit in four positions 90° apart—viz. those which she has about March 20th, the time of the vernal equinox; about June 21st, or the summer solstice; about September 23rd, or the autumnal equinox; and about December 22nd, or the winter solstice; PP' is the axis of the earth, which always remains parallel to itself, directed to the same vanishing point of the heavens. In the position E, at the time of the vernal equinox, the sun appears in the intersection of the equin setual and the ecliptic, whose planes cut the earth in the circles QQ' and KK'; and the poles of the earth fall on the great circle which divides the enlightened from the darkened hemisphere. Hence as the earth rotates on her axis every point of her surface describes half its diurnal course in light and half in darkness i.e. the day and night are equal all over the globe. The same holds good for the position E' viz. at the autumnal equinox. Again at the position T, at the summer solstice, the north pole, with an encircling zone in breadth equal to the angular distance between the poles of the equinoctial and ecliptic, is situated entirely within the enlightened hemisphere, and as the earth rotates on her axis the whole of this part remains constantly enlightened. Hence at this point of her orbit it is constant day at the north pole and the arctic zone; on the other hand, the south pole, with the antarctic zone, is immersed in darkness during the entire diurnal rotation-i e it is constant night. Again, in the remaining regions of the earth it is evident that the nearer a place is to the north pole the longer it will remain in the illuminated hemisphere in the diurnal rotation, every station north of the equator having a day of more and a night of less than 12 hours, and rice rered. for places south of the equator. All these phenomena are exactly

reversed when the earth arrives at the opposite position of her orbit T', at the winter solstice. Now let us remark the changes as the earth passes from one of these critical positions to the next. As the earth moves from E to T, in the northern homesphere the days grow longer and the nights shorter, and consequently the temperature of every part of that hemisphere mereases, and spring is succeeded by summer; in the southern hemisphere the reverse of this takes place. and the transition is from autumn to winter. Again, as the earth moves from T to E' the days and nights approach equality, and consequently the excess of temperature above the mean in the northern and the defect below the mean in the southern hemisphere is reduced: and in the former summer subsides into autumn, in the latter winter is replaced by spring. As the earth passes from E' to T', and again from T' to E, the same phenomena will be repeated, but reversed; the transition being in the northern hemisphere from autumn to winter, and from winter to spring, while in the southern it is from spring to summer, and from summer to autumn.

Second Differences. The differences (corresponding to equal intervals of time) in the successive values of a varying quantity, if the quantity does not vary uniformly, exhibit differences among themselves,—these are called become Differences. Thus, in a series of altitudes observed at equal intervals of time (since the altitude does not vary to the same rate at the beginning, middle, and end of the interval), the differences between them, taken in succession, will generally exhibit second differences. So again with the elements tabulated in the "Nautical Almanac." If these quantities varied uniformly in the interval between the dates for which their values are given, in intermediate value could be correctly interpolated by a simple proportion. The method of "proportional parts" would give the

actual change in the interval between the date of one of the tabulated values and that for which we wish to interpolate. But the rate of varying itself varies during the interval, and hence, when great accuracy is required, the necessity for a correction to the change found by proportional parts, which correction is called the " Equation of Second Differences." The question of finding the second difference is simply the finding the rate at which the rate of varying varies. This may be done by taking two values of the quantity from the table on each side the required one, and setting them down in order; then add together the 1st and 4th and the 2nd and 3rd, observing which sum is the greater; half the difference of the two soms is the second difference. The equation of second differences is found by the help of a table. This correction is of the most importance when the quantity under consideration attains a maximum between two times given in the table. The greatest error that can arise in any case from neglecting it is one-eighth of the whole second difference.

Secondary Circles.—Great circles of the sphere passing through the poles of another great circle, which is called their Primary.

Secondary Meridians. -Mendians of the earth which are determined like the firs' prime, or primary, meridians, such as those of Greenwich, Paris, etc., by astronomical or absolute evidence, independently of the chronometrical or relative method. The primary meridians are those from which the longitude in the tables and on the charts is reckoned; the secondary meridians are useful as fundamental and independent starting-points in making passages.

Sector.—In geometry —A sector of a circle is the figure contained by two straight lines drawn from the centre, and the circumference

between them (Euc iii. def. 10). Sectors of different circles are said to be similar when the sides or bounding radii include equal angles.

Sector.—A mathematical instrument, generally found in an ordinary portable case, with the use of which the navigator should be familiar. It is a universal scale by the aid of which every problem in geometrical drawing may be solved; hence it is of great use in laying down plans and in making diagrams. From its application in graphically working questions in proportion, the French call it the Compass of Proportion. It consists of two equal rulers called legs, which represent the two radii, movable about the centre of the connecting joint, this centre representing the centre of the circle. By opening the legs any sized sector can be obtained. A full description of this instrument will be found in Heather's book on "Mathematical Instruments," vol. i. p. 42 (Weale's Series).

Sector.—An astronomical instrument for measuring the angular distance between two points.

The word is specially applied to the Zenith Sector, a fixed shore instrument constructed for the purpose of determining with great accuracy the meridian zenith distances of stars passing within a few degrees of the zenith.

At sea a portable hand sector is used for taking the altitudes of heavenly bodies above the sea horizon, for finding the distance of heavenly bodies from the moon, and for determining the bearings and distances of terrestrial objects. Such an instrument is known as a quadrant or sextant.

It would be a great advantage, as conducing to consistency of usage and to clear ideas on their construction, if the word "sector" were adopted as a generic term to include all such instruments formed

by two radii of a circle and the intercepted are. These instruments are of two kinds:—(I.) When the length of the graduated are measures the angular distance between the two objects; (II.) When the length of the arc required corresponds to only half the angle between the two objects. The instruments at present used are of the latter kind, those of the former being practically obsolete. There is no confusion in assigning names to the different forms of the first class, but great laxity prevails in speaking of those of the second class.

- (I.) 1. There was the old Common Quadrant, which was merely a graduated quarter of a circle, having a movable radius whereon were two eights for chreeting it to the object; there were two other sights on the fixed initial radius, to be directed to the horizon.
- 2 There was also the Back-staff called D cons's Quadrant, and known to French navigators as the English Quadrant. This consisted of two arcs, the greater containing 60° or 60° between short radii, and the less containing 30° or 25° between longer radii; the two together making the 90° of the quadrant, hence the correctness of retaining the old name.
- (II.) When the principle of the Redecting Sector was invented by Newton and subsequently by Hadley, the old name quadrant continued to be applied by seamen to the instrument, whatever was the length of are with which it was constructed. The term Hadley's Quadrant commonly included both the Octant and Sextont; though these words are strictly applied by the accurate old writer, J. Robertson.
- 1. The Octant has an arc of an eighth of the circumference, and it measures an angle of 90°.

2. The Sextant has an arc of a sixth of the circumference, and it measures an angle of 120°

At the present time what is called the Quadrant is simply a rougher kind of reflecting sector; the limb being about 45°, and the instrument able to measure angles up to 90°, the limit of altitudes. From this latter circumstance, it is supposed, though erroneously, to have derived its name; but in fact, it has inherited this from its predecessors. The word is now colloquially used for any common instrument of the kind of wooden framework, whatever be the length of its arc, in consequence of its similarity in appearance to the old-fashioned quadrant.

The term Sexiant is applied to a more elaborately constructed instrument of exactly the same kind, but of greater extent of arc, and adapted to measure accurately lunar and other angular distances. The form which first came into general use had the arc one-sixth part of the circumference, and this gave the name to subsequent modifications; in the most modern the arc is graduated up to 140 principal divisions, each being equal to half a degree.

Semi.—The Latin prefix indicating the half. Thus we have semicircle, semidiameter, semimenstrual, semihoral, etc. The corresponding Greek prefix is  $\dot{\eta}\mu$ , which we find in hemisphere, hemicycle, etc.

Semidiameter.—The semidiameter of a heavenly body is half the angle subtended by the diameter of the visible disc at the eye of the observer. For the same body the semidiameter varies with the distance; thus the difference in the semidiameter of the sun at different times of the year is due to the change of the earth's distance from the sun, and similarly to the moon and planets. In the case of ratio to the body's distance from the earth's centre; hence the moon is appreciably nearer to an observer on the surface when she is in or near his zenith than when in or near his horizon. The value of the Moon's semi-diameter tabulated in the "Nautical Almanae" is for the horizon and the increase in its value, due to her increase of altitude, is called the augmentation. In taking altitudes and distances of heavenly bodies, the linds of bodies having a visible disc are the subject of observation; therefore to reduce observed altitudes and distances to the apparent altitudes and distances of the centres, the correction for semidiameter must be applied. This is the reason why the semidiameter and not the diameter is given in tables.

Semimenstrual Inequality (L. semi "half"; menstrualis, "monthly," from mensis, "a month") —An inequality (of the tide), which goes through its changes every half month.

Sensible Horizon (L. sensibilis, "that may be perceived through one of the senses"). The plane touching the earth at the station of the observer.—See Horizon.

Serpens (L. "The Serpent" of Ophiuchus).—A constellation lying to the cast of the line joining Arcturus and Antares. a Scrientis, Mag. 2.7, 1896, R.A. 15h 39m, Dec. + 6° 45'.

Set of a Current.—The direction of a current, named after the point towards which it is running. See under Current,

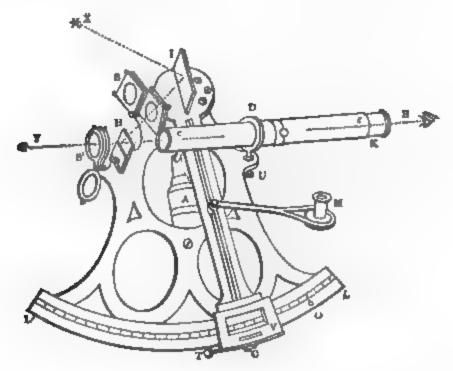

Setting.—A heavenly body is said to be on the point of setting when its centre is in the western part of the celestial horizon.—See Bising.

Setting an Object.—"Setting 'an object is taking a bearing of it. Thus: to set the chase is to observe well the bearing of a vessel chased.

Sextant (L. sections, "the sixth part"). —A portable reflecting autronomical instrument for measuring angles, deriving its name that the reflecting circle) from the extent of the limb, which should be "one sixth" of the circle. -See Sector.

With the aid of the adjoining figure we shall point out the different parts of the instrument under the names by which they are distinguished. LL' is the limb or are graduated from left to right from the zero point 0" through 120"; this is the are proper; the limb is also graduated through a small space, call the arc of excess, in the opposite direction, on the other sale of the zero point the size of the instrument the divisions are cut (on inlaid plates of platinum) at every 10' or 20'; and these are subdivided by the vernier (V, to 10" or 20". The vernier is carried by the index bar IV. a movable radius, which also carries one of the mirrors; T is the tingent-series for giving a minute motion to the index bar after it has been clamped by the clamping screw (C) at the back of the hinb. M is a microscope attached to the index bar by an arm movable round the centre, so as to sweep the vermer through its entire length There are two murors, the index-glass and the horizon glass. I, the index glass, stand upon and moves with the index-bar; it is fixed perpendicularly to the plane of the instrument, in such a position so to be bisected by the axis of revolution produced; H, the horizon glass, is permanently fixed on the extreme radius facing the index glass, with which it should be parallel when the index stands at 0', the instrument being in adjustment; the lower half only of the herizonglass is allvered, the other half allowing objects to be seen through it.

In front of the reflecting index-glass, and before the open part of the horizon-glass, work sets of shades; S the index-shades and S' the horizon-shades: the shades of each set may be used singly or in combination, to moderate the brightness of an image. K is a

telescope (a sextant-case contains several) carried by the collar D, which is a double ring, so constructed as to furnish the means of adjusting the line of collimation of the telescope. This line of collimation, cc, passes through the centre of the horizon-glass, meeting its surface at the same angle as the line drawn from the same point to the centre of the index-glass. Hence a ray of light reflected from the centre of the index-glass to that of the horizon-glass is again reflected along the line of collimation of the telescope. The collar is attached to a stem U, called the up-and-down-piece, by which the

telescope may be raised or lowered till objects, seen directly and by reflection, appear of the same brightness. The two reflectors are furnished with adjusting-screws. A is the handle by which the instrument is held. In the American prismatic sextant the index-glass is replaced by a rectangular prism; and there is no unsilvered portion of the horizon-glass, so that the direct ray passes through no medium.

The principle of the sextant is this:—"The angle between the first and last directions of a ray which has suffered two reflections in one plane is equal to twice the inclination of the reflecting surfaces to "[See Reflection.] Thus let XIHE be a ray of each other." light proceeding from the luminous body X, reflected first from the mirror I in the direction IH, and then again at the mirror H in the direction HE; thus X will be seen, by an eye at E, in the direction Again, another body, Y, lying on this same line of direction, will be viewed coincidently with the reflected image of X by the eye at E through the open part of the glass H. Thus, when their images are brought together, the angular distance between X and Y is double the inclination of the mirrors I and H. This inclination is measured upon the limb of the instrument, and the graduations of the limb are purposely made only half the distance that corresponds to degrees; and thus, when they are regarded as degrees, the reading-off will at once give the angular distance of X and Y instead of half that angle.

The sextant is principally used at sea for measuring the altitudes of heavenly bodies, and the distances of certain of the heavenly bodies from the moon. Held in the hand and requiring no fixed support, it is specially adapted for use on board ship. For altitudes at sea, as no level, plumb-line, or artificial horizon can be used, the image of the body observed is brought into coincidence with the sea offing. The

rextant is the instrument of celo-navigation, and for it the seaman is indebted to Sir Isaac Newton, who first proposed the construction at the beginning of the last century. It is commonly called after John Hadley, who published the invention (made independently by Limself, probably) a few years subsequently. About the same time, also independently, a similar instrument was made by an American glazier, named Thomas Godfrey. As there is frequently a confusion of several different things under the general head of "Adjustments of the Sextant," we must enter fully into its Imperfections, Adjustments, and Errors.

# Sextant: (I.) Imperfections; (II.) Adjustments; (III.) Errors.

- (I) Imperfections, or essential defects which should lead to the rejection of the instrument. The following are the chief points to be tested:—
- 1. All the points of the framework should be perfect, close, and tight, and all the screnz should act well, remaining steady when the instrument is shaken.
- 2. The centering should be perfect. Imperfect centering may be detected by comparing the distance of two stars observed with the sextant under trial with the same distance observed with a standard sextant or circle, or deduced from computation
- 3. The graduation on the limb and cernier should be perfect. It must be noticed that the inlaid plates upon which the divisions are marked are quite level with the surface of the instrument, then the fineness and distinctness of the cutting must be examined with the microscope, and their equality of distance throughout tested by but ing the index of the vernier into exact concidence successively.

CC 2

with each division of the limb, till the last division upon the serner reaches the last division upon the limb; if the last division of the vernier does not in each case exactly collecte with a division upon the limb, the instrument is badly graduated.

- 4 All the glasses used should be perfect. The glasses of the wifetora should be free from veins, and should each have its two faces ground and polished parallel to one another. To test whether this is the case, look with a small telescope into each reflector acparately, in a very oblique direction, and observe the image of some distant object; the image should appear clear and distinct (not notched and streaks in every part of the reflector, and the image single and well defined not misty about the edges. The glass of the shader should in like manner be of the best quality, and each shade have its two faces groun land polished parallel to one another. Each set of shades should also work with all the faces parallel. To cramine the perfection of be shades -Having fitted the dark glass to the eye end of the telescope, without the intervention of any of the index or horizon shades, make a contact of the reflected and direct images of the sun. Then remove the telescope shade, and, setting up first each fixed shape separately, and then their various combinations, observe whether the image remain in contact in each case. Should a divergence be observed a any case, if it occurs when a single shade is used, such shade shade be rejected, if it occurs when a combination is used, the setting of the shades should be altered. This source of error may, however, in allowed to remain, and acknowledged under the head of Shade Error, and corrections applied for it to every observation.
- (II) Adjustments where a contrivance is attached to the instrument by which it may be put into order. We often read, "The adjustments shown be more by an instrument maker, as they require

the greatest care," etc. We entirely disagree with this; every modshipman should learn to adjust his own sextant, and even to re-silver his glasses.

- 1. The "index-glass," or movable reflector at the centre of the instrument, should be perpendicular to the plane of the arc. Criterion.—Having brought the vermer to about 60°, and holding the sextant in the left hand with the face upwards, look obliquely into the index glass, thus viewing the limb by direct vision to the right, and by reflection to the left. The image and the arc itself should appear in the same plane as a single unbroken arc. if the reflection seems to droop from the arc itself, the index-glass leans backward; if it seems to rise, the index-glass leans forward. Means of adjustment.—Screws attached to the reflector.
- 2. The "horizon glass," or fixed reflector, should be perpendicular to the plane of the arc. Criterion. The first adjustment is supposed to be made. Holding the instrument horizontally, look through the telescope and the horizon-glass at a well-defined distant object. The most convenient objects for the purpose are the sea horizon and the sun. (a) When the sea-horizon is used, set the index at zero and give the instrument a slight nodding motion. The reflected image should appear neither above nor below the real object. For this method of testing there must be no index-error, which caution is unnecessary when (b) the sun is used. With the left hand bring the index nearly to the zero point, and move it "handsomely" backward and forward. The image of the sun must pass directly over the object itself: if the image be the lower, the horizon glass leads forward; if it be the higher, the glass leads backward. Means of Adjustment.—Serews attached to the reflector.

- 3. The "line of collimation" of the telescope—i.e. the path of a visual ray passing through the centre of the "object-glass" and the middle point between the cross wires - should be parallel to the plane of the arc. Criterion. - Let the telescope be firmly screwed into its place, and the wires in the diaphragm be set parallel to the plane of the sextant by turning round the "eye-tube." Then (a) fixing upon two distant bright objects from 100° to 120° apart, bring the reflected image of the one to an exact contact with the image of the other object. The angular distance between the two objects is only truly measured when this contact is at the centre point between the wires, which may be tested by noting that the same degree of divergence takes place at the middle points of the upper and lower wires. The sun and moon, when at a considerable distance from each other, are the best objects, and (b) the best practical method of verifying this adjustment is as follows:—Bring the darkened image of the sun to touch the moon, viewed directly, at the middle point of the lower wire, and then, by moving the instrument, instantly bring the point of contact to the middle point of the upper wire: there must be an exact contact here also, the image having overlapped in the centre of If the images appear separated at the upper wire, the object end of the telescope droops: if they overlap, it rises. disarrangement always causes the observed angle to be too great. Means of adjustment.-- The double collar in which the telescope is fixed is furnished with opposing screws, one of which is loosened while the other is tightened.
- 4. For distant objects, when the horizon-glass and index-glass are parallel, the zero of the vernier should coincide with the zero of the arc. Criterion.—The foregoing adjustments being in order, set the zero of the vernier to the zero of the arc, and look at a distant object, as the

should appear to coincide with each other Means of adjustment.— Serews attached to the horizon-glass. If this adjustment is not made, there will be an error in the place of the beginning of the graduation, but this error will affect all angles observed abke. Again, it is only for very distant objects that the direct and reflected images coincide when the mirrors are parallel; for a near object the distance between the mirrors subtends a sensible angle, or has a sensible parallax, and therefore, for every particular distance under about half a mile, a fresh adjustment would have to be made; but it is very objectionable frequently to work adjusting screws. Once more, the expansion and contraction of the bar causes fluctuations in the position of the index. For these reasons it is customary to admit the existence of this source of error, determine its amount, and apply a correction for it, which is called the Index-Correction. See III. 2

- III.) Errors acknowledged and determined, and their effects allowed for or eliminated.
- by perfect ones, or bad setting rectified, the error must be acknowledged and a correction applied. In examining the shades (as pointed out above), if the reflected and direct images of the sun do not many case remain in contact, the angle through which the index must be moved to restore the contact is the error of the shade, or combination of shades used, which error should be recorded for each shade, and each combination of shades. Let s be this angle in any one case, reckoned positive when ranging in the same direction as the graduation of the limb, negative when in the opposite direction; then s, with the contrary sign, is the shade-Correction to be applied to an observation.

2. Index Error (see II. 4) .- The two objects generally used to determine the index-error are (a) the sea-horizon, and (b) the sun-(a) By the sea-horizon.—Holding the instrument perpendicular to the horizon, bring the direct and reflected images of the offing into exact continuation with each other. The reading off r is the index error, reckoned positive if it ranges in the same direction as the graduation of the arc, negative if in the opposite direction; and r, with the contrary sign, is the Index Correction to be applied to an observation. (b) By measuring the sun's diameter. Fitting the telescope and arranging the shades so that the reflected and direct images of the sun may be viewed clearly, and seem of the same brightness, hold the instrument horizontally. The horizontal diameter is chosen, because the vertical one may be distorted by refraction. Now, if the index back placed at 0°, when there is no index error the centres of the reflected. and direct images of the sun will be coincident; when there is an index-error the centres will not coincide. In the latter case, if wecould make an exact superposition of one image upon the other, that reading-off would give us the divergence of the centres, or the indexerror of the instrument. But this cannot correctly by done, and therefore the following method is adopted. Let the left limb of the reflected image of the sun be brought into exact contact with the right limb of the direct image, then read off; again, bring the right hmb of the reflected image into exact contact with the left hmb of direct image, then read off once more. If (as is generally the case) one of these readings is on the arc proper, and the other on the are of excess, half their difference is the index error, and the corresponding index correction is subtractive or additive according as the reading on the art proper is greater or less than that on the arc of excess. Should the readings be both on or both off the arc, half their sum will be the index-correction, subtractive when on, additive

when of, the arc proper. Several sights should be taken on the arc, and the same number of the arc, and a mean of the readings used; also the limbs should be placed (by hand, before the tangent screw is used) alternately a little open and a little overlapping, so that in making the contact the tangent screw may be turned different ways.

3. Parallax-Error — In the geometrical theorems dealing with the construction of the sextant, it is assumed in measuring the angle between two objects that the reflected object is sufficiently distant for the line drawn from it to the centre of the index-glass to coincide practically with that joining it and the eye of the observer. In other words, if with the object as centre and its distance from the centre of the index-glass as radius the arc of a circle be described to cut the line joining the object and observers's eye, this arc is supposed to subtend at the object and observers's eye, this arc is supposed to subtend at the object an angle too small to be appreciable. When however the distance of the reflected object is not great, as for instance less than half a mile, this supposition is no longer permissible, and the angle read off cannot be accepted without correction as the actual angle between the objects. Thus we arrive at the following definition:—

The Parallax of the Sextant for a given object is the angle contained between two straight lines drawn from the object, one to the observer's eye the other to the centre of the index glass.

For small angles up to a certain fixed value between 20° and 30°, which is special for each sextant, the correction is additive, at the fixed value it vanishes, afterwards reappearing with a negative sign. In the first case the line drawn from the eye to the object passes inside the centre of the index-mirror; in the second it passes through the centre; and in the third case outside. The value of the special angle at which the parallax vanishes for a particular sextant may be

obtained by letting fall a perpendicular from the centre of the indexglass upon the line of collimation. The length of this perpendicular divided by the distance of its foot from the eye piece of the telescope gives roughly the tangent of the vanishing angle required

Thus the correction varies both with the magnitude of the angle observed and with the distance of the object. Consequently, if it is wished to obtain an angle between two objects at different distances, that which is further from the observer should be treated as the reflected object, so that the error arising from parallax may be as little as possible.—[See "The Parallax of the Sextant and its influence on Observed Angles," by Captain A. W. Drayson, R. A. in Occasional Papers of the Royal Artiflery Institution 1861, Vol. II. No. 5.)

4. Eccentric Error .- Even the best made sextants are hable to an eccentric error arising from the great difficulty in placing the centre of motion given to the index bar exactly in the centre of the arc, or from the contraction or expansion of the metal. It has no appreciable offect on small angles, but for large ones may amount to several minutes. It has no connection with the index error, and admits of no adjustment A method of finding it is given by Captain H A MORIARTY, C.B. R.S., in his article on Navigation in the Encycle predict Britannica, 9th edition; but the best and most practical plan is to have the instrument tested on purchase, or before going to sea. A special department is maintained at Kew Observatory, for the purpose of examining at a small charge sextants sent by the public and supplying a table of these errors to centering for each 10 of angle. This correction, to distinguish it from the ordinary index correction, is frequently spoken of as "the Kew correction" Every eadet on board H M S "Britannia" is required by Admiralty Order, to obtain such a certificate for his sextunt, and navigators in general are strongly recommended to avail themselves of the facilities thus afforded. The following is a specimen.—

"The Kew Observatory," Rudmond, Surrey. Certificate of Examination.

The sextant 535 of 61 inches radius by Elliot Bros. Londondivided on silver, and reading to 10', has been examined at Kew Observatory.

The telescopes, shades, mirrors and are are found good and the instrument is approved for the determination of lunar distances, latitudes, local times and azimuth, with a maximum error of 20" of arc.

The following are the mean corrections (in addition to the index corrections,

At 15°	<b>3</b> 0°	45°	60°	75	90°	105°	120°
0 10°	-0, 10,	-0' 10"	-0′ 20″	-0' 20"	0' 20	0′ 10″	-0' 10"

Shades.—Sets of coloured glasses attached to astronomical reflecting instruments for the purpose of diminishing the glare of an object, and equalizing the brightness of the direct and reflected images. The set which is fitted to cover the index glass may be called the *Index Shades*, those which are fitted to cover the horizon glass the *Horizon Shades*. If these shades are made of bad glass, and their faces not ground parallel, observations made when they are

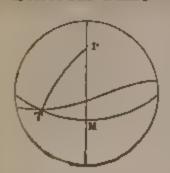

Error. [See under Sextant, III. 1.] Besides these there is the Telescope Shade, a dark glass that can be screwed on to the eye end of the telescope. When this is employed alone there can be no resulting error; for if the faces of the glass are not perfectly ground, the rays from the direct and reflected image are affected alike, and the measured angle between them remains unchanged.

Shaping the Course.—"Shaping" the course is the determining on what course to put the ship's head for a given passage.

**Sidereal** (L. Siderālis, from sidus, sideris, "a star").—Pertaining to the stars; thus we have "sidereal day," "sidereal year," "sidereal time".—See under each term qualified.

The significance of the adjectives must be carefully noted and distinguished in these two sets of expressions. The retrograde motion of the first point of Aries separates it from any fixed star on the ecliptic by 50·1" annually, a quantity which is the express cause of the difference in length of the solar and sidereal year, and which must therefore, in their case, be strictly taken into account. But the corresponding daily motion of the first point of Aries is so small that it is neglected, and the sidereal day is defined by the successive transits of this point. The solar year differs from the sidereal year by reason of the annual motion of the first point of Aries; the solar day differs from the sidereal day by reason of the sun's daily motion in the ecliptic, which is independent of the diurnal revolution of the celestial concave. The first point of Aries, therefore, marks the commencement of the sidereal day and of the solar year.

## "Sidereal Time" at Mean Noon. - The sidereal time at

mean noon, given in the "Nautical Almanac," p. it., of the month, is the time shown by a sidereal clock at Greenwich when the mean solar clock indicates 0h 0m 0s. It may be defined as the angular distance of the first point of Aries from the meridian of Greenwich at the instant of mean

moon (MP τ). It is threefore the same (though reckoned in the opposite direction) with the right ascension of the mean sun when it is mean noon at Greenwich (τ M).

Signs of the Ecliptic or Zodiac.—The ecliptic is divided into twelve equal portions called "signs," each occupying 30° of its circumference, commencing from the vernal equinoctial point, or first point of Aries. The names of the signs, in order, with their several symbols, are as follows: - Aries 7 , Taurus 5 , Gemmi II, Cancer 25 , Leo a. Virgo m : Libra &, Scorpio M, Sagittarius 1, Capricornus 13. Aquarius 22, Piaces s. The first six are the northern, and the last six the southern signs. These are the names also of the twelve Constellations of the Zodiac; and when this notation was established. " the signs of the ecliptic," or, as they are sometimes called, " the aigns of the Zodine," coincided in positions with the "constellations" of the same name, which name, consequently, the sign took. This coincidence, however, no longer exists. The vernal equinoctial point, or first point of Ames, from which the divisions of the ecliptic commence, has a slow retrograde motion along the ecliptic, so that it is no longer in the constellation of Aries, but is now a tunted in that of Pieces, and so for all the "signs" whose position is defined by

of the origin; they have retrograded with respect to the corresponding constellations, or, which is the same thing, the constellations have progressed relatively to them, the constellation of Aries now occupying the sign Taurus, the constellation of Taurus the sign Gemini, and so on. Hence it must be particularly observed that the signs of the ecliptic are now regarded as purely technical subdivisions, and not to be confused with the constellations of the same name, though they were originally identical. In former times it was usual to note the longitude of a heavenly body in signs, degrees, minutes, etc., 5s 15° 20' indicated what would be now written 165° 20'. The old nomenclature still, in some measure, holds its ground. equinoctial points are generally called the first point of Aries, and the first point of Libra; the two parallels of latitude on the earth's surface called the tropics retain the names of the Tropic of Cancer and the Tropic of Capricorn, after the constellations in which the solstitial points were formerly situated; and again, in speaking of the place of the sun, it is often referred to the signs—"the sun is in Aries," means that he is between 0° and 30° of longitude.

Sirius (Gk.  $\Sigma \epsilon l \rho los$ , from  $\sigma \epsilon l \rho \epsilon l \nu$ , "to scorch"; or Canicula, L. the "Dog Star").—The star a Canis Majoris, the brightest in the heavens. In ancient times the heliacal rising of this star (i.e. the period of the year when it rises so much before the sun as to become visible just before daylight) followed close upon the summer solstice, the season of the greatest heat. The Egyptians called it "Sothis," and from its heliacal rising had warning that the overflow of the Nile was about to commence. Owing to the precession of the equinoxes, the heliacal rising of Sirius has slowly changed, its date at present taking place about August 10.—See Canis Major.

Slack-water. The time of slack-water at any place is that interval during which there is no tide-current. It must not be confounded with the time of high or low water.

Small Circles. -Small Circles of the Sphere are those whose planes do not pass through the centre. See under Circles.

Solar (L. solaris, from sol, "the sun") —Pertaining to the sun. Thus we have the Solar System, designating all those heavenly bodies which revolve about the sun as their centre. Again, the Solar Year and Solar Dan are portions of time marked and defined by the apparent motions of the sun; so we have Solar Eclipses, the Solar Disc, etc.

Solstices (L. solstitium solis states, from sol, "the sun," and store "to stand still') The two periods of the year, about June 21st and December 22nd, at which the sun attains his maximum declination north and south. When the sun, in his annual revolution in the ecliptic, after travelling north, has attained his greatest northern dechaation, his course for the moment is parallel to the equinoctial, and, as far as change of declination is concerned, he appears "to stand still"; and similarly he appears "to stand still" when at his greatest southern declination. They are distinguished as the Summer Solstice and the Winter Solutice We must bear in mind, however, that these terms are relative, for what is the summer solatice in the northern is the winter solatice in the southern hemisphere, and what is the winter solstice in the northern is the summer solstice in the southern lamisphere. Hence, at first sight, it would appear better to distinguish the solstices as the northern and southern solstice, but then the significance of these epochs would be lost They are, be it remembered, epochs of the tropical year, which year has especial reference to the succession of the seasons, and therefore, as in the case of the equinoxes, the seasons which they mark must be the qualifying adjective; thus, as we have the Vernal and Autumnal Equinoxes, so we must have the Summer and Winter Solstices. In cases where there is any danger of ambiguity or confusion, we may add northern or southern, as the case may be: thus one date will be called the Northern Summer Solstice or the Southern Winter Solstice, and the other the Northern Winter Solstice or the Southern Summer Solstice. It is convenient to restrict (as we have done) the term solstice to indicate a date or epoch of time; and to use the expression solstitial point when we want to refer to a position or place in the ecliptic. Similarly for equinox and equinoctial point.

Solstitial Colure.—The hour-circle which passes through the solstitial points. On it are situated not only the poles of the equinoctial, but also those of the ecliptic.—See Colures.

Solstitial Points.—The two points of the ecliptic at the greatest distance from the equinoctial. They are distinguished as the Summer Solstitial Point and the Winter Solstitial Point, and called also the First Point of Cancer and the First Point of Capricorn, as being the commencement respectively of these signs of the ecliptic. They are represented by the symbols of these signs & and &. The figure of the Crab (Cancer) has evident reference to the change in the direction of the sun at this point of his orbit. The solstitial points, like the equinoctial points, do not preserve a constant place among the stars, but have a regular slow retrograde motion.

Sound.—Whatever be their loudness or pitch, all sounds are propagated with the same velocity through the same medium. This velocity has been determined for the atmosphere by experiments.

The conclusion arrived at is that sound travels in dry air, at the temperature of freezing water, about 1090 feet per second; and that, supposing the pressure of the atmosphere constant, the velocity increases with the temperature at the rate of 1 14 feet (very nearly) per second for every 1° Fabrenheit. At an average temperature of 62°, sound will travel at the rate of 1125 feet per second.

Whatever tends to increase the dasticity of the air also accelerates the motion of sound through it. A moderate breeze direct between the origin of the sound and the listener affects the velocity about 20 feet a second. It is obstructed by whatever disturbs the homogeneity of the medium, such as partial variations of temperature. Sounds are better heard during the night than in the daytime; and snow, fog, and rain, when general, are particularly favourable for the transmission of sound. These facts furnish a method which is sometimes convenient for estimating distances. If the number of seconds be noted which clapse between seeing the flash of a distant gun and hearing the report, the distance of the gun is easily deduced. The following approximate rule is useful for practical purposes: - Divide the seconds elapsed by 5; from the quotient subtract 12 of itself, and the result is the distance in statute onles very nearly; if the of the quotient be added instead of subtracted, the result is in nautical miles.

Sounding (Sax. sond "a messenger"; Fr. sonder; Sp. sondar or sondear).—Sounding is the ascertaining particulars respecting the bottom of the water through which a ship is sailing. The results of ocean sounding will doubtless prove indirectly important to the seaman, but for the direct purposes of navigation we are concerned only with (I) Soundings in shallow water, with a view of safely

guiding the ship over shoals, through channels, to an anchorage, etc.; (2) Soundings in deeper water, with a view of determining the position of the ship.

- I. In Safety-Soundings it is evident that it will often be sufficient to know that the depth is above a certain value, but when it shallows to near the draught of the vessel, great attention must be paid to the soundings. They are found by the simple instrument called the Hand-Lead.
- 2. In Position-Soundings the information is sought on two points—the depth of the water and the nature of the bottom. instrument used is the Deep-sea Lead. In the common deep-sea lead the depth of the water is indicated by the length of the measured and marked line run out, and the nature of the bottom is ascertamed by the portion brought up by the "arming" of the lead. To obviate the necessity of stopping the ship's way and "rounding her to" when thus sounding, several ingenious instruments have been invented. In Burt's Buoy and Nipper the line runs through a spring catch in the buoy till the lead reaches the bottom, when the catch seizes the line and fixes the buoy at the depth descended. Massey's Lead registers the depth of water descended through by wheelwork set in motion by a fly. Walker's Harpoon Sounding Machine is on the same principle. Ericson's Lead measures the depth of the water by the space into which the air contained in a glass tube and reservoirwithin the lead is condensed by the pressure of the water. Sir William Thomson's Sounding Machine has a glass tube connected with the sinker, closed at the top end and coated inside with chromate of silver; the increased pressure at greater depths drives the water up the tube, and its action leaves a white mark, the position of which

can be estimated by a scale; planeforte steel wire is used instead of line and is coiled on a light reel. The methods of estimating the depth by the increased pressure, being independent of the amount of line out, do not necessitate stopping or reducing the speed of the vessel. See Lead.

South Frigid Zone — The zone of the earth contained between the south pole and the antarctic circle, or parallel of about 66° 33′ S.

South Temperate Zone The zone of the earth contained between the tropic of Capricorn, or parallel of about 23° 27 S., and the autoretic circle, or parallel of about 66° 33' S.

South Point of the Horizon.—The north and south points of the horizon are the points in which the meridian line meets the celestial horizon, the south point being that adjacent to the south pole of the heavens. When the north pole is above the horizon, the south point is sometimes taken as the origin from which azimuths are reckoned.

South Pole of the Earth - That pole which is farthest from Europe.

South Pole of the Heavens That pole of the heavens towards which the south pole of the earth is directed.

**Southern Hemisphere.** Of the two hemispheres into which the earth is divided by the equator, the *southern* is the one in which Europe is not situated.

Southing.—The distance a slap makes good in a south direction; it is her difference of latitude when going southward. Opposed to northing.

Sphere.—(Gk. σφαῖρα, "a ball").—A solid contained by one uniform round surface, every point of which is equally distant from a certain point within it called the centre; it may be conceived as generated by the revolution of a circle about a fixed diameter. The doctrine of the sphere treats of its properties considered as a geometrical surface. In astronomy by "The Sphere" is commonly understood the "Celestial Sphere," or "Concave." The Right Sphere is the sphere in that position in which the diurnal circles are at right angles to the horizon; the Parallel Sphere the sphere in that position in which they are parallel to the horizon; and the Oblique Sphere, the sphere in that position in which they are oblique to the horizon.

sphere of the Heavens, or of the Stars.—The imaginary sphere of infinite radius, having the eye of the spectator for its centre, on the concave surface of which the heavenly bodies appear to be placed. It is also called the "Celestial Concave." The radius of the earth being evanescent relatively to the distance of the celestial concave, the eye of the spectator and the centre of the earth are considered coincident.

Spherical Sailing.—The method of solving problems in navigation upon principles deduced from the spherical figure of the earth. All problems not involving difference of longitude may be determined upon the supposition that the elements all lie on a plane requiring the application of plane trigonometry only; hence the relations of the quantities, Course, Distance, Difference of Latitude, and Departure, are treated of under the head of Plane Sailing. The aid of spherical trigonometry, either in the actual computation or in the construction of the tables used, is necessary when the Difference of longitude is involved, and hence the relation of any two of the quantities, Course, Distance, Difference of Latitude, and Departure,

Spherical Saurag. The simple case of Parallel Saurag (where a property of the sphere exhibits a constant relation between the Departure and Difference of longitude, which two quantities may therefore be treated as elements of a plane triangle) farmishes a kind of link between plane and spherical sailing. From this particular case is deduced an approximate method of solving the general problems of spherical sailing called Muddle-Lambde Sailing. The accurate method is called Mercator Sailing, from the chart constructed on the principles made use of. See Sailings.

Spheroid (Gk σφαιροειδής, "ball like"; from σφαίρα, "a ball," and είδος, "form"). -A solid body which approaches the form of a sphere. It may be conceived to be generated by the revolution of an ellipse about one of its axes. If the ellipse revolve about the major axis, a Prolate Spheroid is generated; if about the minor axis, an Oblate Spheroid. The oblate spheroid is the more important, as being the form which a mass of plastic matter would assume by rotating on a given axis, and consequently it is the form of most of the heavenly bodies.

Spica. (L. "an ear of corn").—The name of the bright stor a l'irginis, so called after the device of the an ient Greeks, who placed an ear of corn in the the hand of the Virgin, typical of the barvest, which with them coincided with the sun's approach to this conspicuous star. See Virgo.

Spiral Curves.—Curves which circulate round a point or pole following some distinguishing law. On the surface of the carth an equiangular spiral is a curve which cuts all the mendants at equal angles while it winds round and round the globe approaching the pole asymptotically, it is best known as the chumb.

Spring Tide (Sax. springan, "to grow," "bulge").—The greatest tides, taking place after the syzygy of the sun and moon.—See under Tides.

Stars, Fixed.—Those bodies of the heavens which possess a high degree of permanence as to apparent relative situation. The term "fixed" must be understood in a comparative and not in an absolute sense, as doubtless every body of the universe is in a state of motion. In consequence, however, of their enormous distances, the proper motions of the "stars" produce an extremely small apparent change of relative positions to an observer on the earth's surface, and for all practical purposes they are appropriately designated as fixed. Their apparent position is also unaltered (except in a very minute degree in some few cases) by the parallactic change of view caused by the motion of the earth in her orbit, though she shifts her place by about 180 millions of miles in the course of the year. The nearest of the fixed stars, a Centauri, is distant about 200,000 times the distance (about 93 millions of miles) of the earth from the sun, others are perhaps 1000 times more remote; and in consequence they appear, when viewed through the most powerful telescopes, only as bright points without any apparent disc. They shine by their own light like our sun, and their twinkling at once distinguishes them from the planets, which are visible merely by reflected solar light. The stars exhibit different grades of brightness, and are hence ranged by astronomers into classes called "magnitudes." [See Magnitude.] The telescope reveals to us that the stars are innumerable, but it is only with the most conspicuous that the navigator is concerned. These are marked out into artificial groups called "constellations," and each member of such group is distinguished by a letter of the Greek alphabet, and in some cases by a proper name. It is necessary for us to acquire a knowledge of the names and positions of such fixed stars as are useful in the problems of celo-navigation, of which stars full particulars are given in the "Nautical Almanac."

- 1. We may do this by calculating the distance of the first point of Aries from the meridian of our station at any given hour, and ascertaining, by means of the catalogue of the right ascensions and declinations, what stars must at that time be above the horizon and near the meridian, and then, by comparing their right ascensions and declinations, we may easily learn the name of each particular star. In consequence of the sun's motion in the celiptic (in direction contrary to the diminal motion), the fixed stars rise earlier every successive night
- 2. The simplest plan, however, of becoming acquainted with the stars is by means of a globe or map of the heavens. One or two remarkable groups (such as Ursa Major and Orion) can be at once recognized, and then we can refer any star, the name of which we wish to know, to some other stars already known, by imagining a line to pass through two or more such known stars, and, when produced to a certain distance, to pass through or near the star whose name is required.
- 3. The Malky Way is also of great assistance to scamen in finding a star, especially on a bright night.

The altitudes of stars may be most advantageously observed at sea during the twilight, as the horizon at that time is in general clearly visibly and strongly marked.

Star Charts. The zone in the vicinity of the equinoctial may conveniently be mapped down on Mercator's projection. This is an

important portion of the heavens, especially in connection with finding the longitude by lunar distances. We have consequently given a chart to illustrate Lunar-Distance Bodies. This is necessarily on a very small scale, but every young officer can draw a large one for his own use. The chart given comprises a zone of 90°; and it shows the lunar-distance zone of 60°, with the ecliptic and zodiac running athwart it.

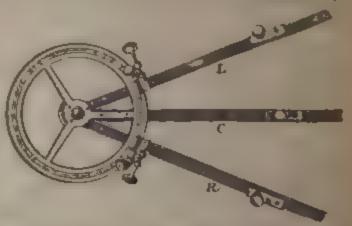

Two are given in the commencement of this book for north and south declinations. Each includes 90° of the heavens, viz. 45° from the pole. These charts are mounted as circular rotating discs, and by setting them the appearance of the heavens in the regions delineated can be obtained for any date at the place of observation. It will be easy for any navigator to construct similar discs on a larger scale.

Stars, Magnitude of—The classes into which astronomers have distinguished the fixed stars, according to their apparent brightness. This apparent brightness is the combined result of their distance from us, their actual size, and their degree of heat. The classification is entirely arbitrary and conventional, and different observers differ in the magnitude they assign to the same star. The brightest stars are said to be of the first magnitude, including about 23 or 24 principal stars; then come stars of the second magnitude, which exhibit a marked falling off in brightness from the first class, numbering about 50 or 60; stars of the third magnitude come next, comprising about 200; and so on down to the sixth or seventh, the numbers belonging to each increasing very rapidly as we descend in the scale of brightness. The sixth and seventh magnitudes include the smallest stars visible to the naked eye on the clearest and darkest night. The classes which follow, from the seventh and eighth to the sixteenth

form a separate division, being that of the telescopic stars. difference of lastre between stars of two consecutive magnitudes is so considerable as to admit of intermediate gradations being acknowledged. At the first introduction of fractions into the nomenclature of brightness, a simple intermediate stage was recognized, thus a star intermediate in brightness to a star of the first and second magnitude, was described by a combination of the two figures, as 1.2 m; one between the second and third as 2.3 m; and so on. The interval was afterwards sometimes trisected, thus -1 m, 1.2 m, 2.1 m, 📴 m; where 1.2 m represents a star whose magnitude is intermediate, but nearer the first than the second; 2.1 m a star whose magnitude in intermediate, but nearer the second than the first. This was the method adopted in the table of Standard Stars given in the " Nautical Almanac " More lately a decimal subdivision has been proposed in the place of these rougher forms of expression, and has been introduced in the Nautical Almanac of 1896. As this change may be overlooked, it is well to draw attention to it, remarking that the dot used previously to 1896, is not a decimal point, and is therefore printed on the level of the line and not higher up as a decimal point is placed. Thus the magnitude of a Cygni is described in N.A. of 1895 as 2.1. but in N.A. of 1896 as 1.5; and that of a Piscis Australia, respectively as 1.2 and 1.3 The magnitudes in N.A. 1896 are taken from the Harvard Photometry or the Uranometria Argentina These are the results of contrivances for measuring light photometric Catimates Stellar photometry was initiated by Sir William Heischel and provided with exact methods by his son Sir John. Extended photometric catalogues have since been constructed on opposite sides of the Atlantic at Harvard by Professor E. C. Pekering and at Oxford by Professor Pritchard. In Herschel's catalogue the apparent leightness of a Centauri was selected as a unit of measurement. In later lists unity does not describe the greatest brightness, which is now found on the negative side of zero. Sirius is by far the brightest star in the heavens, its brilliancy being four times that of an average list magnitude star. It stands in a category alone; its magnitude will be found represented in the N A. for 1896 as -1.4 while that of Arcturus is given as 0.0. The next six in order are Capella, 0.2; Vegation 2; Rigel, 0.3; Canopus, 0.4; Procyon, 0.5; and a Centauri, 0.7. Then follow Achernar, 1.0; Aldebaran, 1.0; Altair, 1.0; and Antares, 1.1; Pollux, 1.1; Spica, 1.2; \$Centauri, 1.2; a Crucus, 1.3; Fomalhaut, 1.3; Regulus, 1.4; a Cygni, 1.5; c Canin Majoris, 1.5; Castor, 1.6. Betelguese varies from 1.0 to 1.4.

Station Pointer. An instrument for laying down the position of a place from which have been observed two horizontal argues

subtended by three distant objects. It may be applied with great advantage to lay down the position of a ship as she passes a well surveyed coast, or approaches a known but

hidden danger. In its usual form it consuts of a graduated rug connected with its centre, from which radiate three arms one edge of each being bevelled. The middle arm is fixed, the edge coincidus with the zero of the graduations which are thence reckoned and marked on the are in both directions. The two other arms usual movable, the one to the right the other to the left through any and

round the common centre. Where they pass outward under the graduated circle they carry vermers furnished with clamping and tangent screws for fixing them and accurately reading off the angle.

When the two angles observed have been set upon the ring, the instrument is laid on the chart so that the bevelled edges of the three arms pass through the positions of the observed objects, the centre will then indicate the position of the place of observation; and this is marked off by passing a pricking point through a small opening made at the centre for the purpose. A small piece of tracing paper may be made to serve in the absence of this instrument. Mark on it a point to represent the station of the observer, and from this draw three lines, the right and left making with the central one the two observed angles. Then laying the tracing paper on the chart, thift it about till the three lines all pass respectively over the three objects observed. Prick through the point where the lines meet and the required position will be thus marked on the chart. The principle of the station-pointer will be found explained under the Three point Problem.

Stereographic Projection (Gk. orepeds, "solid"; γραφείν, "to grave".—The stereographic projection of the sphere is a natural projection of the concavity of the sphere on a diametrical plane as primitive, the eye being placed on the surface at the opposite extremity of the diameter perpendicular to the primitive. See under Projection.

Storms, Law of.—Revolving storms or cyclones (including the Hurricanes of the West Indies and South Indian Ocean, the Typhoons of the (hims Sea, and the Storms of the Bay of Bengal) appear to be subject to a law of which the two following points are the characteristics: (1) The wind revolves in a spiral curve round and towards an axis with great rapidity, in a direction against the hands of a watch.

in the northern and with the hands of a watch in the southern hemisphere: the nearer the centre or vortex the more violent is the wind, while the centre itself is calm, the barometer descending as the centre is approached. The diameter of this whirl or gyration is in some cases as much as a thousand miles, while in others it is only a few leagues. (2) While thus rotating, the storm is carried bodily along, the axis leaning forward. These storms originate somewhere between the parallels of 10° and 20° north and south, and first travel westward in both hemispheres, increasing, however, their distance from the equator until they reach the parallel of 25° or 30° north and south, when they turn towards the east or "recurvate," but continue to increase their distance from the equator; -in other words, they first travel westwardly, inclining towards the nearer pole, and then recurve and travel eastwardly, still inclining towards the pole, The rate at which they advance appears to be different in different seas, and also to depend upon the age or period of the progress; 200 miles a day is an average rate, but in some cases it approaches 1000 miles a day.

When a ship is caught in one of these revolving storms, the great object is to avoid the vortex, where the sea is most confused, and where a sudden and violent change of wind occurs from an opposite quarter. If the ship scuds, she will obviously run round and round the vortex; if compelled to heave-to, that tack should be selected on which the wind draws aft, because, from the extreme violence of the wind, there is danger, if it head the ship, of her getting sternway: while the ship can run, the object should be to make for the nearest limit or edge of the storm. Running, however, is attended with risks (being dismasted, upsetting, broaching-to), especially in higher latitudes, where the path of the storm is variable. The

following is the rule for determining the bearing of the centre, given in the Admiralty Remarks on Revolving Storms, 1853:—" Look to the wind's eye; set its bearing by the compass; take the 8th point to the right thereof, and that will be the bearing of the centre of the storm, if in north latitude; or if in south latitude, the 8th point to the left of the direction of the wind."

It is advisable on the first warning of the approach of a cyclone to heave to, in order to determine accurately its position and motion. The manner in which the wind is veering is an important indication. The samplest way to understand how the wind veers as a carcular storm passes over the ship is the following .- On a circle mark the chrection of the whirl (for the hemisphere) by arrows; and draw a diameter in the direction of the track of the storm, which may be deduced approximately from the locality. It must be borne in mind that, for both hemsepheres, the track curves in the opposite direction to the whirl. It is the relative motion of the progression and of the ship (hove-to) with which we are now concerned, and we may therefore consider the storm to be at rest and the ship to be moving in the contrary direction. If we then pass a pencil along any chord of our whirl disc in the opposite direction parallel to the track of the storm, this will point out to us how the wind veers in any part of it. It will thus be found that the wind always veers in the same direction as the storm rotates, on that side of the path which is external to its curvature; and in the opposite direction within the curvature. If we note therefore how the wand is veering, we shall be able to conclude in what part of the storm we are hove-to. The star discs of the commencement of this volume may serve as storm whirl-dises, the direction being the same for rotation of stars and of wind in each hemisphere.

Stratus (L. "land flat"). -The "Flat Cloud," one of the primary modifications of cloud. -See Cloud.

Stray-line —The waste portion of the log line which while the log-ship is getting clear of the eddy caused by the See under Log.

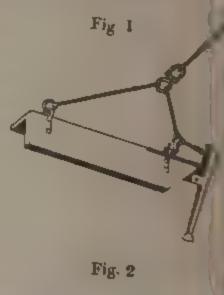

Submarine Sentry. A machine invented by Mandames, c. x., for giving instant and automatic warning when enters water of a specified depth, thus guarding against the distranding as the water shouls.

The sinker or kite consists of two pieces of board screwed

at right angles and pointed at one end. On the ridge formed by the meeting of the boards are fixed two rungs, and towards the pointed and it has a groove cut into it to receive a atrong spring passing between the attachments of the ring and terminating in a hook Into this ring is booked an iron trigger, the other end of which projects beyond tha pointed end of the wood and passes through a hole at the top "the striker", retained in this position by the spring. The striker is an iron rod working upon a hinge fixed to the wood; its bottom being hollowed to received the " arming " of the ordinary deep-

soa lead.

The whole is slung

by two wires: one being permanently attached to the ridge; the other holding on temporarily to the trigger and being liberated when the trigger slips from the hole at the top of the striker. These two wires meet in the ring of a swivel to which is attached the fine single piano wire, of the highest tenacity attainable, by which the kite is towed from the slip's quarter. The requisite number of fathoms of this wire are here coiled on a drum.

The sinker is, what it has been called, a veritable kite—a wooden inverted one and it dives in the water on the same principle that a paper kite rises in the air. Its two elings form "the belly-band" by which the requisite inclination is secured. The kite is towed astern at any specified depth up to 45 fathoms, the vertical depth to which it sinks depending on the length of line let out and the angle to the horizontal at which it is made to trail. The curve formed by the wire while towing is concave downwards, and its form is not changed when the ship's speed is altered within practical limits, the kite not trailing further astern and varying its depth when a given length of wire is out. This is an important feature of the sentry, that the vertical depth is not altered by a change of speed, between 5 and 13 fathoms. This depth is indicated on a a dial attached to the drum. The steadmess of the sentry on guard is evidenced by the point where the line enters the water never varying in relative position.

When the vessel enters water of the depth for which the instrument is set, the striker touches the bottom (Fig. 2.), and the blow impelling the top forwards instantly withdraws the projecting end of the trigger, and relieves the lower sing of the kite, which at once rises to the surface and trails astern with ridge uppermost. The moment of striking is indicated on board by the sudden loss of tension of the wire sounding a gong attached to the drum. While in action the vibration of the towing wire causes a continuous rattle in a sounding box and the cessation of this noise gives an additional indication that the "sentry" has struck bottom.

Two kinds of kites only are issued with the machine, the one (ordinarily used) painted black, for depths down to 30 fathoms; the other, painted red, set at a deeper angle and specially designed for use at depths between 30 and 45 fathoms.

Although the primary object of the apparatus is to act as an under-water sentry, trailing for any length of time at a set depth, it may be advantageously used to take single soundings up to 45 fathoms, while the ship is under weigh. To do this set or cock the striker by connecting the trigger and sling, put the kite over the fair-lead, and pay out slowly with a hand on the brake. The gong will sound the instant the bottom is touched and the vertical depth read off on the dial without waiting to haul in.

For full description and explanation of principle, see Lecture by Professor C. J. Lambert M.A., at the Royal United Service Institution, June 3rd 1891; Journal, Vol. xxxv., No. 161. [James' Syndicate Limited, Offices 18 Billiter Street, London, E.C.]

Summer Solstice.—With reference to the northern hemisphere, the summer solstice is that period of the year when the sun attains his greatest northern declination—about June 21st.—See Solstices.

Sumner's Method.—The method of finding a ship's position at sea by the projection of the "line of equal altitude" on a Mercator's chart is named after Captain Thomas H. Sumner, U > N.

At any moment the sun is passing through the zenith of a ne place on the earth's surface. If with a radius of any magnitude we describe a circle round the point in question, all places situated upon this circle will at the given instant have a zenith distance equal to the tadais assumed. When therefore we obtain the sun's zenith distance by observation of the altitude, the information derived is this-that the ships place lies upon a certain circle, to whi h the name of Parallel of Equal Altitude was assigned by Captain Summer, and which has also been called a Cocle or Parallel of Pession And if after waiting till the sun's bearing has changed by some points a second observation be made, we deduce another circle on which also the place of the ship is situated. The intersect on of these two circles gives the place of the ship. There will of course be two such points of intersection, but the DR position of the ship will fell us which is the one required. The pair of circles may also be thous corresponding to the altitudes of any two bodies observed at the same time; and two bright stars taken at twilight are very useful for the purpose.

This is the general principle of Summer's method of finding the position. The place of the slap is letermined by the intersect, in of two circles. In practice we cannot actually describe the circles in the Mercator's Chart, so we resort to the following artifices.

## 1. The Churt Method

Having taken an altitude we assume two latitudes, one about '' greater, and one about 10 less than the DR latitude; and determ so by calculation the longitude corresponding to each, marking more

the parallels of latitude made use of the positions indicated by these longitudes. These two points will each lie upon the circle of equal lititudes upon which the ship is situated. And by joining the two points we obtain a line called appropriately a line of position, which is assumed to coincide practically with the arc of the circle of equal altitude. By treating the second observation in the same manner we arrive at another line of position, the intersection of which with the first line will determine the position of the ship.

For this reason, the name of Astronomical Cross Bearings is sometimes applied to the Sumner Method; and, as with the terrestrial cross bearings, the angle of intersection should be as nearly a right angle as possible.

The following example, with figure, will afford an illustration of the Chord Method.

In latitude by account 53° 13' N., and longitude by account 5° W. the following results were obtained from two altitudes of the sun.

First Altitude.

Second Altitude.

Lat. 53° N., Long. 4° 50′ W. Lat. 53° N., Long. 5° 20′ W.

Lat. 53' 30' N., Long. 5° 2' W. Lat. 53° 30' N., Long. 4° 43' W. The figure is here drawn, for convenience, on a somewhat small scale:

in practice a larger scale of chart used is desirable.

On the parallel of 53° N. we mark off the point A corresponding to long. 4° 50′ W.: on that of 53° 30′ N. we mark off A¹—corresponding to 5° 2′ W., and join the two points by the line AA¹.

6'W 53' 30'N A1 B1 4'W 53' N B A 4'58' W

Repeating the operation with the longitude 5° 20' W. we obtain B on the parallel of 53° N., and with longitude 4° 43' W. a point B' on the parallel of 53° 30' N and joining these two points we have a second line BB'; the intersection of which with the first line gives the point P in lat. 53' 19' N, and long. 4° 58' W., as the place of the ship.

## 2. The Tangent Method.

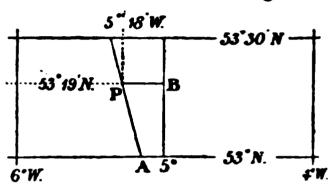

In the previous case it was assumed that the chord joining two points taken fairly close together upon a circle coincides with the arc. The method about to be described is based upon the assumption that for a short distance the tangent drawn through a point taken upon the circumference of a circle will coincide very nearly with the arc of the circle. We proceed as follows—

The point assumed, through which the tangent will be drawn, is that indicated by the DR latitude and longitude of the ship. If the body is near the Prime Vertical, with the assumed latitude we calculate the longitude, and mark on the chart the position obtained. But if the body is near the Meridian, instead of working a longitude by chronometer with the assumed latitude, we, for the time being, consider the longitude correct, and by an ex-meridian method find the latitude corresponding to the given altitude and hour angle, marking the point obtained upon the meridian assumed. And since our circle of position has the sun for its centre, the direction of the tangent will be at right angles to the line of bearing of the body, which may be obtained either by calculation, or, when possible, by the Burdwood and Davis Tables. For instance if the sun bears E.S.E., the line of position will run N.N.E. and S.S.W., and so on.

The following example illustrates the practice of the tangent method-

In latitude by account 53° N., longitude by account 5° W., the bearing of the sun being N. 76° E., the longitude was found from an observed altitude to be 5° 10′ W. Later in the forenoon, working with longitude 5° W., a second altitude reduced to the meridian gave latitude 53° 20′ N; the sun's bearing, as taken from Tables, being S.5° E.

The first observation gives a position line N. 14° W. which accordingly is drawn through the point A (lat. 53° N., long. 5° 10′ W.). The second observation has its position line S. 85° W.,

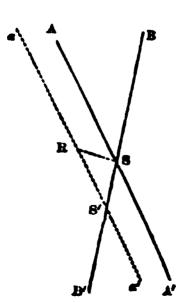

which drawn through the point B (lat. 53° 20' long. 5° W.) cuts the first line at P in lat. 53° 19' N., long. 5° 16' W., which is the position of the ship required.

In the observations hitherto worked, it has been assumed that no change has taken place in the ship's position between the observations. When however such change has taken place, the first line of position will have to be adjusted so as to take the "Run" into account.

The correction is made as follows—Taking any point, at S, in the first line of position, AA' lay off a line SR, to represent the "Run" in magnitude and direction. Through the extremity of this line draw a straight line, aa', parallel to AA' and this will be the corrected line of position required. The intersection of aa' with the second line of position, BB', will give the correct position of the ship S'.

One of the most important and generally useful applications of the Summer process is

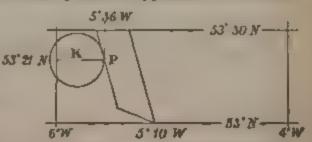

when in the vicinity of land. Though the absolute position of the ship may be undetermined, one line of equal altitude may serve to give her distance from the shore, when the coast trends parallel to this line. Whe approaching the land, the ship's place may be found by combining this one line of equal altitudes either with soundings or with the line of bearing of some point given in position, as for instance a light-house.

As an example of the former may be cited one of special interest; Commander Sullivan on entering the River Plate found a line of equal situade, and identified the ship's position on it in 12 fathoms by means of the chart.

In the latter case, the lantern of a light-house may be regarded as corresponding to a celestial body; and the circle engraved on a chart shewing the boundary which limits the range of the beacon light is analogous to the terminator of a system of circles of equal altitude for the sun. Where the light appears on the horizon, the ship must be somewhere on the range circle of the light house and the point where this is intersected by the circle of equal altitudes gives the position of the ship. But as the light rises its bearing will more conveniently give the second line of position. The following example will illustrate the method, as well as the practical application of the Run.

In latitude 53° N an observation taken when the sun's bearing was 53°2′ N N. 76° E, gave longitude 5° 10′ W. The slup then ran 14 miles N. 66° W.,

when the Kish light K (lat. 53° 21' N., long 5° 54' W.) came into view bearing due West. Required the ship's position. Answer 3° 21' N; 5° 36' W.

In practice, the chord method, or as it is sometimes called the "Double Chronometer" observation is virtually obsolete. To work out the four longitudes and lay off the necessary lines of postion would take as much time as to work a " Double Altitude " proper, with one "longitude by Chronometer," which would have been the ancient method of determining the place of the ship with the same data. And it should be remembered that the processes of Spherical Trigonometry are absolutely rigorous and true; whereas the Sumner Methods give at the best approximations only, so that some caution is necessary in dealing with them. The assumption, for instance, that the chord or tangent coincides for short distances with the circuinference of the circle is only justifiable so long as the radius is reasonably large. The Sumner process therefore should be avoided when the altitude is higher than 60°. And there is another matter in which some caution is necessary. It is of the utmost importance, in the application of the tangent method that

Longitude aights should be worked for latitude:

Longitude aights should be worked for longitude.

As has been already pointed out, if an observation is taken near the Prime Vertical, we must assume DR latitude, and calculate longitude, marking our position on the parallel. If near the meridian, we must assume longitude and calculate latitude, marking our position on the meridian. And by a happy compensation, when, through the body diminishing its bearing an observed altitude loses its merite as a longitude observation, it becomes advantageous for finding latitude; and new versal. The following practical rule will enable us to determine whether an object is suitably attracted for finding latitude by the method of Reduction to the Meridian.—The number of minutes of time in hour angle should not be greater than the number of degrees

in the zenith distance. In exceptional cases, near the equator particularly, it may happen, as in the example worked out to illustrate the chord method, that both observations are near enough to the Prime Vertical to be worked out for longitude; but the case is exceptional, and it is much more common for one to be near the Prime Vertical and the other near the Meridian.

A variation of the tangent method has been proposed by certain French writers, known as the "New Navigation." In the "New Navigation," both latitude and longitude are assumed for the time to be correct, and the zenith distance corresponding to the ship time at the moment of observation is calculated. From the point on the Chart, indicated by the assumed latitude and longitude, a line is drawn directly towards or from the place of the body as marked by its true bearing, and from this line a distance is cut off equal to the difference between the observed and calculated altitudes. The line of position is drawn through the point at right angles to the line of bearing of the body. This method however seems to offer no special advantages, and in this country, at all events, has not come into general use, though interesting from an academic point of view. When made use of, it should be confined to observations near the Meridian, thus taking the place of the latitude by ex meridian.

Captain Summer reduced his method to a system, and published it at Boston in 1843, under the title of "A new and accurate method of finding a ship's position at sea by Projection on Mercator's Chart." And it is not detracting from his credit or from the pride which his countrymen feel that "this discovery has been made by an American ship master," to remark that the principles involved were by no means novel, and were practically applied by others independently about the same time; for example, in the same year by Commander

Sullivan, R.N., and discussed subsequently, but also independently, by J. N. Laverry, Naval Instructor, R.N. It is only, however, within the last twenty years that the processes have been put into general practice, their adoption having been very greatly facilitated by the publication of the Burdwood, Davis and other Azimuch Tables, which enable the navigator to obtain a heavenly body's True Bearing by simple inspection instead of by a tedious calculation.—See under Positions, Parallels of.

Sun (Sax. sunna; Latin analogue, sol, whence solar).—The vital centre of that group of heavenly bodies of which our earth is a member. Its actual diameter is about 109 times that of the earth, or 860,000 miles, and its mean distance from us no less than 23,584 times the length of the earth's radius, or about 93,300,000 miles. The apparent diameter varies from 31' 32" (in the beginning of July) to 32' 36'4" (in the beginning of January), and the horizontal parallax is 8'76". The figures here given are from Report of Astronomer Royal on Transit of Venus, 1874. The sun is the most important body for the purpose of celo-navigation; and full particulars are given respecting it, for every day in the year, in the "Nautical Almanac." Each column must be thoroughly understood. Symbol  $\odot$ .

Superior (L.).—An adjective often used to qualify scientific terms, indicating "above," "upper," "outer"; and opposed to Inferior, which indicates "below," "lower," "inner." Thus we have the superior tide when the moon is above the horizon, the superior culmination of a circumpolar star, the superior planets whose orbits are external to that of the earth, and the superior conjunction of an inferior planet.

"Swinging the Ship."—An operation for determining the deviation of the compass on board ship. There are two principal methods of conducting it.

1. The magnetic bearing of a conveniently distant object being latermined, the ship is carefully awang to each point of the compass, and on each the bearing of the object is noted. The difference atween the magnetic and the observed bearing will be the deviation or each point.

The magnetic bearing of the object is found: (a) By taking the mean of those observed bearings that are on equidistant points, the fects of deviation being thus eliminated; or (b) By carrying the moderd compass on shore to some place (free from "local attraction") here the distant object and the position of the compass on board to exactly in the same line with the observer's eye. This is ridently the same as the magnetic bearing of the object from the map.

The object selected should be at such a distance that the diameter the space through which the compass revolves in swinging makes sensible difference in the bearing

2. A more reliable method ("Reciprocal Bearings") is to call in he aid of a second compass, placed on shore, beyond the influence of he iron on board the ship. The two compasses should be compared taking the bearing of a distant object with each of them on shore, he shore compass should not be further off from the ship than is onestent with distinct visibility, with the naked eye, of both impasses from each other. As the ship's head is then successively rought to each point of the compass, as indicated by the compass on sard, an observer on shore takes the bearing of the compass in the imacle, and a person on board simultaneously (the instant being nown by concerted signal) takes the bearing of the compass on tore (indicated by a flagstaff). Each bearing observed from the

ship is afterwards compared with the opposite of the corresponding bearing from the shore, and the result is a table of deviations for every direction of the ship's head. If during the operation a hase obscures the shore-compass, while the sun at the time is shining brightly, a number of points may be secured by time-azimuths, which otherwise might be lost.

Time-azimuths are also advantageous when the second of the above methods cannot be used for want of an assistant observer for the shore-compass; and when the first of the above methods is not available owing to the length of the ship and the scope of moorings, combined with the most distant objects in sight not being sufficiently far off to render the difference of their bearings insensible as the ship swings round to the tides. In such cases Godfray's Azimuth Diagram will be found very useful.

Syzygy (Gk. συζυγία, "a yoking together"; from συν-, "together," ζυγὸν, "a yoke").—The position of the sun, earth, and other moving bodies, when their projections on the plane of the ecliptic are in one line. By the syzygies of a planet or of the moon are meant those points of its orbit at which the body is in conjunction or opposition with the sun; the two points when the body appears 90° from the sun being distinguished as the quadratures. "The moon in syzygy" expresses the position both of conjunction and opposition, the time both of new and full moon; and the term, consequently, is a very handy and appropriate one in speaking of the tides.

Syzygy Tide.—The tide which takes place on the afternoon of the day the sun and moon are in syzygy: if the syzygy takes place when the sun or moon is on the meridian, the tide is particularized as the Meridianal Syzygy Tide.—See under Tide.

## T.

t,—Of the letters used to register the state of the weather in the log-book, t indicates " Thunder."

Taurus, Constellation of (L. "The Bull").—The second constellation of the ancient zodiac, lying between Aries and Gemini. This group is easily identified in the heavens, as it contains the two beautiful little clusters of minute stars called the Hyades and the Pleindes; and in the former is situated the bright ruddy star a Tauri named also Aldebaran. A line joining Aldebaran and Sirins is bisected by the middle star of Orion's Belt. a Tauri, Mag 1.0; NA 1896, R.A 4h 30m, Dec. + 16° 18′ \$ Tauri, called also Nath, is near the bisection of the line joining Betelgaese and Capella; Mag 1.9 N.A. 1896; R.A. 5h 20m, Duc. + 28° 31′

Taurus, Sign of. The second division of the ecliptic, including from 30° to 60° of longitude. Owing to the precession of the equinoxes, the constellation Taurus in no longer in the sign of that name, the constellation Aries having taken its place. The sun is in Taurus from about April 20th to about May 21st. Symbol 8.

Temperate Zones (L. temperatus, "moderate").—The two zones of the earth meladed between each tropic and the adjacent polar circle, or parallels of latitude of about 23° 27° and 66° 33° north and south. In these zones the sun never appears vertical, but in every durinal revolution he ruses and sets; hence their temperature is in a general way intermediate between that of the Torril and that of the Frigui Zones, and they thus derive the name by which they are commonly distinguished.—See Zones.

Terminator.—The surface of the earth regarded with reference, to its illumination by the sun is divided for any one instant into two parts, one enlightened and the other in shade. The corrections for parallax, refraction, and semidiameter being made, these portions are hemispheres, and they are are divided from each other by a great circle. This great circle is called by older writers, such as Robertson, the Terminator, from its property of "terminating" or bounding the verges of light and darkness. This term has the advantage of brevity as well as of analogy to the word equator. By most modern witers the name given to it is The Circle of Illumination; a term descriptive and appropriate, but rather cumbersome. The word "Terminator" has also the advantage over the other of being capable of extension to a star, if it is defined as the boundary of the hemispheres in one of which at any moment the body is visible and in the other invisible.—See Position, Parallels of.

Terrestrial (L. terrestris, from terra, "the earth").—Pertaining to the earth; opposed to Celestial. Thus we have the "Terrestrial Meridian" of an observer, and the "Terrestrial Horizon," as distinguished from the "Celestial Meridian" and the "Celestial Horizon"; again, we have the "Terrestrial Equator" and the "Celestial Equator," "Terrestrial Longitude and Latitude" and "Celestial Longitude and Latitude."—See under each term qualified.

Theodolite (coined from Gk. θεάομαι, "I survey "δόλος,, "a stratagem").—The most important instrument used by surveyors. It is an altitude and azimuth instrument, and by the combination of the means of measuring simultaneously vertical and horizontal angles, it gives at once the angular distances between objects projected on the plane of the horizon. There are two essential parts of the theodolite:—

- 1. The horizontal limb consisting of two circular plates fitting accurately and turning freely upon one another round a vertical axis; the edge of the lower disc is graduated with the divisions of the circle, and the upper one has chamfered portions of its arc formed into verniers.
- 2. The vertical limb, generally a semicircle, carrying above its diameter the observing telescope, works upon a horizontal axis which is supported upon a frame embedded in the vernier plate and turns with it in azimuth. The semicircle is graduated on one side from 0° to 90° each way, and on the other side there is a given scale for reducing the distances measured along the ground at various elevations and depressions, to the corresponding distances projected on the horizon.

The stand, levels, compass, telescopes, and other necessary fittings would require lengthened description. For this and for the different adjustments we must refer to special books on the subject as "Mathematical Instruments," by J. F. Heather (Crosby, Lockwood and Co.).

Thermometer (Gk.  $\theta\epsilon\rho\mu\delta$ s, "hot";  $\mu\epsilon\tau\rho\epsilon\delta$ s, "to measure").

—An instrument by means of which temperature is measured. The principle upon which its construction depends is, that within certain limits bodies expand or contract with the increase or decrease of the degree of temperature to which they are subject. The common thermometer consists of a closed glass tube with a capillary or barrlike bore, terminating in a bulb at one end; the bulb and part of the tube contain mercury or colored spirits of wine, the part of the tube not so occupied being a vacuum. A graduated scale is attached to

the tube to indicate the expansion of the mercury or alcohol, which expansion is considered to be proportional to the degree of heat by which the instrument is influenced. The thermometer generally used in England is called after Fahrenheit of Amsterdam, who first constructed mercurial thermometers. His inferior limit of temperature was an intense degree of cold, produced by a mixture of snow and sea-salt, and which, as if it were the greatest degree of cold possible, he marked as the zero of his scale; his superior limit was the boiling point of mercury, which he marked 600°. On this scale the freezing point of water is 32° and the boiling point of water (under a certain atmospheric pressure) is 212°. In the thermometer constructed by Réaumur with spirits of wine, the freezing point of water is the inferior limit, marked 0°, and the boiling point of water (under a certain atmospheric pressure) the superior limit, which is marked 80°. A much more convenient scale is the Centigrade, invented by Celsius, a Swede. The two limits are the same as Réaumur's thermometer, "the freezing point" being obtained by immersing the instrument in melting snow; and "the boiling point" by exposing it to the steam of water boiling under a given atmospheric pressure; the freezing point is marked 0° and the boiling point 100°, the intermediate space being divided into a hundred equal parts.

To compare the indications of a Fahrenheit, Réaumur, and Centigrade thermometer.—Under the same circumstances let the three thermometers indicate respectively F°, R°, and C°. Then, F—32° is the number of degrees of Fahrenheit above the freezing point, and (since  $212^{\circ}-32^{\circ}=180^{\circ}$ ) a degree Fahrenheit measures the  $\frac{1}{180}$  th part of the distance between the freezing and boiling point, also a degree Réaumur measures the  $\frac{1}{80}$  th part, and a degree Centigrade the  $\frac{1}{180}$  th part of the same distance.

$$\therefore \frac{\mathbf{F} - 32}{180} = \frac{\mathbf{R}}{80} = \frac{\mathbf{C}}{100}$$

Hence 
$$\frac{F-32}{9} = \frac{R}{4}$$
;  $\frac{F-32}{9} = \frac{C}{5}$ ;  $\frac{R}{4} = \frac{C}{5}$ 

formulæ by means of which we can deduce the reading of one scale from that of another,

It may be noted that the three scales are connected by the equation

$$F = C + R + 32^{\circ}.$$

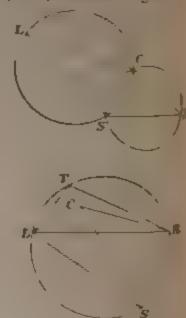

An expression which is especially worth remembering in view of the fact that on the continent many thermometers have the Réaumurscale upon one side of the tube, and the Centigrade upon the other.

Three-Point Problem.—In a marine survey, to determine the position of a station, S, from which have been observed the angles subtended by two pairs, R and C, L and C, of three known objects R, C, L, the object C being between the right one R and left one L, There are two methods of solution of this problem: (1) the "Two Circle Method," and (2) the "Straight Line and Circle Method." They both depend on Euclid iii. 21.

Join R and C, C and L; on the lines R C, C L, describe segments

of circles containing angles respectively equal to those subtended at S by R and C and by C and L. (Euc in 33). The segments will intersect at the required station S.

(2) Joining the two extreme objects R and L, make the angles RLT, LRT respectively equal to the angles subtended at S by R and C, and by C and L. About the triangle RTL describe a circle (Euc. v. 5); join TC, and produce TC till it cuts this circle The point of intersection will be the required station S.

The general principle which should govern the selection of the objects to be observed is that the cutting arcs of the segments, above described, should intersect as nearly as possible at right angles; the centres of the two circles being some distance apart. The two observed angles, therefore, should each be near 90', and no angle less than a third of this should be admitted unless the central object a very distant compared with the other two.

To obviate the long process of protracting, an instrument has been invented by the help of which the station of the observer of the two angles may be expeditionally fixed; or this may be accomplished in a simple manner, with the aid of a piece of tracing paper. Station Pointer.

Tides (Sax. tidan, "to happen"; from tid, "time").—Semi-diurnal oscillations of the ocean occasioned by the combined action of the sun and moon. The relative effects of these two bodies are directly as their mass, and inversely as the square of their distance; and the moon, although very small in comparison with the sun, is so much nearer that she exerts by far the greater influence on the phenomena of the tides. We may consider their action separately.

The attraction of the moon on different parts of the earth is less as the distance is greater, and thus it influences the parts of the occan hearest to her more powerfully than the body of the earth, and th's again more powerfully than the waters most remote. particles of water under the moon have a tendency to leave the earth. but are retained by the superior attraction of the earth; again, the moon attracts the centre of gravity of the earth more powerfully than she attracts the particles of water in the hemisphere opposite to her, so that the earth has a tendency to leave these waters, which are retained, however, by the superior attraction of the earth. The effect of this difference of the attractions on the superficial water on opposite sides, and in the central mass, gives two risings of the water the one vertically below the moon, and the other diminetrically opposite to this place. If the earth were entirely covered with an ocean the waters would thus assume the form of a spheroid, having, if the earth had no rotation, its longer axis directed towards the moon, and its shorter axis at right angles to that direction. As the moon in her apparent diarnal motion looks down successively upon each meridian, the protuberance of the ocean follows its motion from east to west; but, by reason of the mertia of the water, this occurs at a merulian about 30 to the east of the moon. This great wave, following all the motions of the moon, is modified by the action of

The sun raises a similar but much smaller wave, which tends to follow his motions, and which consequently at times combined with the lunar wave, and at other times opposes it, according to the relative position of the two bodies. It must be particularly noted that the bodies do not draw after them the water first raised, but continually tend to raise that under them at the time | The tide | not a circulating current, but an immensely broad and excessively fatwave, which is propagated by the transits of the disturbing body. As this wave strikes our coast the water gradually elevates a self to a certain height, then as gradually make to about the same extent below its mean level; and this oscillation is continued constantly, with certain variations in the height and in the times of attaining the maxima of elevation and depression. Considering the tries. relatively to the whole earth and open seas, on the meridian about-30° to the east of the moon there is high-water, on the west of this circle the tide is flowing, on the east it is ebbing, and on every part of the meridian at 90° distant it is low-water,

Pides, Neap (Sax. neafte, "searcity").—The smallest tides being the result of the action of the moon and sun when they are conflicting. They take place after the moon is in quadrature— to after the first and third quarter of the moon. The smallest neap total happen when the moon's and sun's attractions tend most to counteract each other, which will happen when the moon's action is the less possible and the sun's the greatest possible. This will evidently be (1) When the moon is in apogee and the earth in perihelion at or next the same time; or, in other words (as the parallax of a body indicated its proximity to the earth, when the moon's parallax is the less, while the sun's is the greatest; (2) When the moon's declination and the latitude of the place are of different names, and the declination and

the greatest possible, at the same time that the sun's declination coincides or approximates to the latitude of the place, both being north or south; or, in other words, when the moon's meridian altitude is the least possible and the sun's the greatest, the action being the more powerful in proportion as the body is more nearly vertical. The magnitude of the tide is also affected by strong winds and the state of the atmosphere. The action of the former is most conspicuous in rivers and narrow seas; and of the latter it has been observed that a rise in the barometer of an inch has been accompanied by a depression in the water of the tide of twelve or fourteen inches.

Tides, Spring (Sax. springan, "to grow," "bulge"). -The greatest tides being the result of the action of the moon and sun when they are co-operating, they take place after the moon is in syzygy-Le, in conjunction and opposition, when it is new and full moon, The greatest spring tides happen when the moon and sun are in such positions that their attractions produce the greatest effect upon the waters, especially when these positions are contemporaneous. These are-(1) When the moon is in perigee; when the earth is in perihelion. In other words (as the parallax of a body indicates its proximity to the earth), the effect of each body in raising the tide is greater as its parallax is greater. (2) When the moon's declination coincides with or approximates to the latitude of the place, both being north or south, and the sun's declination fulfils the like condition. In other words (as, generally speaking, the vertical action is the most powerful), the effect of the two bodies is greater as their altitudes are greater. The magnitude of the tide is also affected by strong winds and the state of the atmosphere ; favourable winds and a low barometer are the meteorological conditions which summent the tides.

Tide, Superior and Inferior.—The Superior Tide is that which takes place in the hemisphere which has the moon above the horizon; the Inferior Tide is that which happens simultaneously in the hemisphere which has the moon below the horizon.

Tide-wave.—The accumulation of the waters of the sea which is caused by the action of the moon, modified by that of the sun, changes its position through the day. The moon and the sun in their diurnal revolutions continually and successively tend to raise the water beneath them at the time, and thus the alteration in the level of the sea is propagated from east to west, though there is no transference of the water itself except near the shore. Interruptions in the regular propagation of the tide-wave are caused by the depth of the ocean and the barriers presented by land stretching athwart its direction.

Tide-current.—The current in a channel caused by the alteration of the level of the water during the passage of the tidewave. Thus there is the Current of the Flood and the Current of the Ebb; Slack-Water intervening at the change from one direction to the other. The tide-current does not generally change with the tide; thus, under certain circumstances, the current of the ebb continues to run for some hours after the flood-tide has made.

Tide, Range or Height of.—The difference between the level of high-water and that of low-water. Speaking of the earth at large, the range is greater in those latitudes over which the moon and sun pass vertically, being very small in high latitudes. In the open ocean the range is inconsiderable, and in inland seas almost insensible. It is most affected by local causes, as the shoaling of the water and

the narrowing of the channel, especially if the channel opens in the direction of the tide-wave; thus in the Bristol Channel the range is above 40 feet.

Tide, Retard or Age of. - The interval between the transit of the moon, at which a tide originates, and the appearance of the tide itself. It is found in general that any particular tide is not due to the moon's transit immediately preceding, but to a transit which has occurred some time before, and which is said therefore to correspond to it. The Retaid of the Tide is thus distinguished from the Lamitedal Interval, which is the interval between the moon's transit and the high-water next following. The name Returd is derived from the tide appearing to be "retarded" in following the moon in her diurnal course. The cause of the phenomenon may, however, be best understood by regarding the actual rotary motion of the earth on its axis, instead of the apparent diurnal revolution of the moon in the heavens. The momentum of the water will cause a continuance of its rise long after it has passed under the exciting cause. On the same principle, changes in the parallax and declination of the sun and moon produce their several effects on the time and height of the tide, not immediately, but after certain intervals.

Tide, Tide and Half-tide, Tide and Quarter-tide.—
In the open sea high and low water succeed each other at intervals of about 6h 12m; such interval is designated "a tide." In channels where a tide-current is formed, when the stream continues to flow up for 3h after it is high water, it is easid to make "a tide and half-tide"; if it continue to flow during 1h 30m after high-water, it is easid to make "a tide and quarter-tide," and so on.

Tide-day, Priming and Lagging.—The tide-day is the interval between two successive arrivals at the same place of the same vertex of the tide-wave. It varies in length as the waves due to the separate action of the moon and sun approach to or recede from coincidence, the resultant maximum being at a point intermediate between them. The lengthening and shortening of the tide-day on its mean is called the *Priming* and *Lagging* of the tide.

Tide. Histablishment of the Port.—The sun and moon being in the same relative position, the time of high-water is different for different ports, owing to the inertia of the water and the obstructions it meets with from the friction of the sea-bed, and the narrowness, length, and direction of the channels along which the wave has to travel before reaching the port. It is of great maritime importance to be able to find the time of high-water for harbours and ports, and to this end a standard tide is fixed upon, indicated by a particular relative position of the moon and sun, from which the time of every tide may be deduced. The standard is called the " Establishment of the Port," and is the time of high-water at full and change of the moon at the given port reckoned from apparent noon. It is the actual time of high-water when the moon passes the meridian at the same time as the sun, or the interval between the time of transit of the moon and the time of high-water on full or change days. It may be determined roughly by observation on the day of full or change, and is, in this case, distinguished by Whewell as the "Vulgar Establishment of the l'ort." The "Corrected Establishment of the Port" is the interval between the time of the moon's transit and the time of the tide not on the day of syzygy, but corresponding to the day of It may be determined by observing the intervals of the times of the moon's transit and the times of tide every day for a

semi-lunation, and taking the mean of these, If we know by how much the transit of the moon to which the tide corresponds is antecedent to the transit next preceding the tide, the corrected establishment may be obtained from one observation of any tide. The establishment for a large number of important stations is published by the Hydrographic Department of the Admiralty in special tables. Hence may be deduced the time of high-water for any day at the given place. Thus, if on a particular day the sun and moon pass the meridian of the given place at the same moment, and the interval be observed from this to the high-water next succeeding, we get the apparent time of high water at the meridional syzygy. On the day following the moon will have moved about 48m in right ascension more than the sun, and will therefore pass the meridian that much later than on the first day. Now, if the lungfidal interval or period between the moon's transit and the high-water next following be the same for the two days (as it will be nearly if we take into account the action of the moon only), the apparent time of high water on the second day will evidently be the apparent time of high-water on the first day + the apparent time of the moon's meridian passage on the second day. This is the general principle in the solution of the problem; the details and corrections need not here be noticed. The Establishment of the Port is spoken of by Robertson as "The Time of the Nyzy gie High-water for the given Port," which may be abbreviated into " Syzygy Tule", similarly it has been called the " Change Tule," a term, however, objectionable as expressing either too little or too much; for if the word "change" be extended in meaning to include the time of full as well as of new moon, it ought logically to embrace

also the first and third quarters, which in the case before us must be expressly excluded. Raper uses the term "Tide-hour," and the German analogue is "Hafenzeit," "Harbour-time."

Time.—A definite portion of duration. It is marked in a general manner by the recurrence of striking natural phenomena, such as the alterations of light and darkness, and the succession of the seasons. Thus the two natural measures of time are the day or period of the earth's rotation on her axis, and the year or period of the earth's revolution in her orbit.—See Calendar.

Time, Common and Local.—Common Time is reckoned from an epoch (or initial instant) independent of local situation—such is that known among astronomers as equinoctial time, which is the same for all the inhabitants of the earth. Local time is reckoned at each particular place from an epoch determined by local convenience, such as the transit of the sun's centre over the meridian of the place; what is called Greenwich Time and Ship Time are both examples of local time.

Time, Diurnal.—The day depends upon the rotation of the earth on her axis, but this is indicated to a spectator on the surface only by the apparent revolution of the celestial concave in the

opposite direction. Diurnal time is, therefore, defined by the motion of some chosen point in the heavens as it appears to revolve from east to west, and is measured by the angle at the pole of the heavens between the celestial meridian and the hour-circle passing through the point of definition reckoning westward. Thus we have Sidereal

Time, Apparent Solar Time, and Mean Solar Time, according as the

point of definition is the first point of Aries (7), the actual sun (8), or the mean sun (M). Sidereal Time is measured by the angle at the pole of the heavens between the celestial meridian and the hour-circle passing through the first point of Aries (QPT); and similarly for Apparent Solar (QPS) and Mean Solar Time (QPM).

Time, Equation of -See under Equation.

Time, Equivalents.—Two tables are given in the "Nautical Almanae" pp. 502—505; the first for converting intervals of mean solar time into equivalent intervals of adereal time, the second for converting intervals of adereal time into equivalent intervals of mean solar time. They are constructed from the formulae:—

$$M + .002738 M = 8...(1)$$

$$8 - .002731 \ S = M . . . (2)$$

These tables also serve as Tables of Acceleration and Retardation, by taking the difference between each argument and its equivalent.

Time, Ship.—The mean solar time at the place where a ship happens to be, as contrasted with Greenwich Time. In east longitude it is evidently before Greenwich Time, in west longitude behind Greenwich Time; every 15° of longitude making a difference of one hour.—See Longitude in Time.

Time, Azimuth — An azimuth determined by calculation from these data—the latitude, the declination, and the "hour angle." This is the problem the approximate solution of which is furnished by the Burdwood and Davis' Azimuth Tables. An altitude azimuth is an azimuth determined by calculation from these data—the latitude, the declination, and the "altitude." -See under Azimuth.

Time-balls.—Balls dropped down a staff at observatories, to notify certain preconcerted times, 1 P.M. being that in general use. They are of great use to navigators for determining the error and rate of their chronometers.

Tornado (Sp. and Port. tornada).—A storm characterized by its whirling motion.—See under Storms.

Torrid Zone (L. torridus, "parched").— The zone of the earth included within the tropics or parallels of latitude of about 23° 27' N. and S. Twice every year the sun is, at noon, close to, if not actually in, the zenith of every place in this zone; consequently the temperature is exceedingly high in this portion of the globe, and hence the name by which it is commonly distinguished.—See Zones.

Transit (L. transitus, "passage across").—By the "transit of a heavenly body" is commonly understood its passage across the meridian of the observer's station; a "Transit Instrument" is a telescope moving in the plane of the meridian, and therefore adapted for observing these transits of the heavenly bodies. By the "transits of an inferior planet" (Mercury or Venus) is understood the passage of its dark body across the luminous disc of the sun; and similarly the "Transits of Jupiter's satellites" describes the phenomenon when his satellites are observed as dark spots to pass across the illuminated disc of the planet.

Traverse Sailing.—The case in plane sailing where the ship makes several courses in succession, the track being zigzag, and the directions of its several parts "traversing," or lying more or less athwart each other. For all these actual courses, and distances run on each, a single equivalent imaginary course and distance may be found which the ship would have described had she sailed direct for the place arrived at. Finding this course is called "Working a raverse." The plane sailing formulæ—

Dep. = 
$$dist \times sin course \dots (1)$$

Diff. lat. 
$$=$$
 dist.  $\times$  cos course . . . (2)

give for each course and distance the corresponding departure and difference of latitude; and taking the algebraic sum of all the departures and of all the differences of latitude, we get the required course from the formula—

Tan course = 
$$\frac{\text{dep.}}{\text{diff. lat.}}$$

and then the distance from either of the formulæ (1) and (2). A table called the *Traverse Table* is used to obviate the necessity of computation.

The following form, illustrated by an example taken from Raper, will be found convenient in working a traverse.

Example.—A ship sails S.W. by S. 24 miles; N.N.W. 57 miles; S.E. by E.1E. 84 miles; and S. 35 miles—find the course and distance made good—

Courses.	7	Diff.	Lat. D		ep.
	Dist.	N.	S.	E.	w.
Pts.					
S. 3 W.	24	<b> </b>	20.0	_	13.3
N. 2 W.	57	52.7	<b>—</b>	_	21.8
8. 5½ E.	84		39.6	74·1	_
South.	35	-	35.0	_	_
		52.7	94.6	74.1	35·1
			<b>52·7</b>	35.1	
			41.8	39.0	

Using the Traverse Table, the Diff. lat. 41.9 and Dep. 39.0 are found at 43° against the Dist. 57. Hence, since the ship has made southing and easting on the whole, the resultant course is S. 43° E., and the distance 57 miles. Problem.—To find the latitude in and longitude in, having given the latitude from, the longitude from, and the several courses and distances run between the two places. By working a traverse the difference of latitude and the departure are obtained. Hence, by applying the difference of latitude to the latitude from, we have the latitude in. The middle latitude is then found, and the solution of the problem completed by the aid of the formula of spherical sailing—

Diff. long. = dep.  $\times$  sec. mid. lat.;

the difference of longitude applied to the longitude from, giving the longitude in.—See Plane Sailing.

Traverse Table.—A table so called from its use in traverse sailing. It contains the true difference of latitude and departure corresponding to every course (at intervals of a quarter-point and also of degrees) from 0 to a right angle, and every distance up to 300 nautical miles (at intervals of one mile). It is constructed by solving a right-angled triangle, of which one angle represents the course and the hypothenuse the distance; by giving these parts different and successive values, the corresponding values of the other two sides are found, which sides represent the true difference of latitude and the departure. It is evident that the difference of latitude and departure for any course are the departure and difference of latitude for the complement of that course, and hence the table is compactly arranged by interchanging the headings of the columns containing these elements at the top and at the bottom of the page, and using the top reading for courses from 0° to 45°, and the bottom reading for

courses from 45° to 90°. This Table may be used for a large number of problems depending for their solution on the relations of several parts of a right angled triangle, as for instance in the case of the "Correction for Run."

Triangles, Solution of.—The problems of geo-navigation (except great-circle sailing) all depend upon the solution of plane triangles. The problems of great-circle sailing and all those of celo-navigation depend upon the solution of spherical triangles. If therefore the general trigonometrical formulæ for the solution of triangles, plane and spherical, be remembered there is no occasion to burden the memory with any verbal rules for the particular problems of navigation. In what follows the three angles of the triangle are called A, B, C, and the sides respectively opposite to each a, b, c.

- 1. Plane Triangles, Formulæ.—In every plane triangle A + B + C = 180°.
  - (1) Right angled Plane Triangles, Let A be the right angle
- (1) The relations of the three sides are given by the formula  $a^2 = b^2 + c^2$ . If b and c are given,  $a = \sqrt{b^2 + c^2}$ ; but as this form cannot be adapted to logarithmic computation it is only exceptionally used for very simple examples. The general method is first to determine one of the angles B or C. If a and one of the other sides is given, as b, then  $c = \sqrt{a^2 + b^2} = \sqrt{(a + b)(a + b)}$ .  $\log c = \frac{1}{2} \log (a + b) + \log (a b)$ .
- (2) The relations of the sides and angles are given by the formula  $\operatorname{Sin} B = \frac{b}{a}$ ;  $\operatorname{Cos} B = \frac{c}{a}$ ;  $\operatorname{Tan} B = \frac{b}{c}$

and their reciprocals. And C 90° - B.

. L. Sin B - 10= $\log b - \log a$ , L.  $\cos B - 10 = \log c - \log a$ ; L.  $\tan B - 10 = \log b - \log c$ .

TABLE L

Case.	Given.	Required.	Trigonometrical Formulæ.
1	Three sides a, b, c,	Three angles A, B, C	(1) $\sin \frac{A}{2} = \sqrt{\frac{(s-b)(s-c)}{b \cdot c}}$ Where $a+b+c$
			or (2) $\cos \frac{A}{2} = \sqrt{\frac{s(s-a)}{b \cdot c}}$
			or (3) $Tan = \sqrt{\frac{(s-b)(s-c)}{s(s-a)}}$
			or (4) Hav A = $\frac{(s-b)(s-c)}{b \cdot c}$ (with table of $b \cdot c$ Haversines) Similarly for angle B.
<b></b> .			For C, A+B+C=180°
11.	I'wo sides and the angle opposite to one of them a, b, A	Remaining angles and side B, C, c	$\frac{\sin B}{\sin A} = -; C = 180^{\circ} - (A + B)$ Sin A a  [Where $a > b$ , since the greater angle is opposite to the greater side, $A > B$ , and B can be determined. When $a < b$ , there are two values of B and the case
			is ambiguous. $\frac{c}{a} = \frac{\sin C}{\sin A}$
III,	Two sides and the included angle a, b, C	Remaining angles and side A, B, c	Method i. First determine A and B $ \frac{A+B}{2} = \frac{180^{\circ} - C}{2} $ $ \frac{A-B}{2} = \frac{a-b}{a+b} \cot \frac{C}{2} $
			c sin C
			$\frac{-}{a} = \frac{-}{\sin A}$
			Method ii. First determine c.
			$c=(a-b) \underbrace{\begin{array}{c} C \\ sec \theta \end{array}}_{a+b} \operatorname{sec} \theta$
			where $\tan \theta = \frac{1}{a-b} \tan \frac{1}{a}$
			$\frac{\sin A}{\sin C} = \frac{a}{c}$
īv.			$\frac{\sin C  c}{C = 180^{\circ} - (A + B)}$
14.	One side and two angles	Remaining angle and	$b \sin B c \sin C$
	<i>a</i> , A, B	two sides (C, b, c	$-=\frac{1}{a};  \overline{a}  \overline{\sin A}.$

(ii) Triangles other than Right-angled. These can be solved by one of the following formule.

(1) Sin 
$$\frac{A}{2} = \sqrt{\frac{(a+b)(a+c)}{bc}}$$
 where  $x = \frac{1}{2}(a+b+c)$   
(2)  $\frac{a}{b} = \frac{\sin A}{\sin B}$ ; (3)  $\tan \frac{1}{2}(A+B) = \frac{a}{a+b}$ . Cot.  $\frac{C}{2}$ 

(2) 
$$\frac{a}{b} = \frac{\sin A}{\sin B}$$
; (3)  $\tan \frac{1}{2} (A - B) = \frac{a}{a + b}$ . Cot.  $\frac{C}{2}$ 

The several cases are arranged in the annexed Table I, according to the data: when three sides are given, when two sides are given wild an angle, and when one side is given with two angles. The I war th mio expressions are also written at length, embodying the tales used in navigation,

II Spherical Triangles, Formulæ. - (1) Right appel Transfes. All the formula for these triangles are compassed unler Napier's two rules. Let A be the right angle : leaving this out, the "circular parts" are  $b, c, \frac{\pi}{2} + a, \frac{\pi}{2} + B, \frac{\pi}{2}$  C. If M be the mass of part, A,, A,, the "adjacent parts," and O,, O, the "apposite parts | then

Sin M = 
$$\tan A_1$$
,  $\tan A_2$   
Sin M =  $\cos O_1$ ,  $\cos O_2$ .

The "middle part" is always selected so that the other two pass are either both "adjacent" or both "opposite" Having written down the equation, make a dash under the part required; its na, intude (whether greater or less than 90°) is determined by placing over the known parts their proper algebraical signs.

(ii ) Quadrantal Triangles. Rules analogous to the above equals apply to these. Let a be the quadrantal side; leaving this out, the "circular parts" are B, C,  $\frac{\pi}{2}$ , -A,  $\frac{\pi}{2}$ , -b,  $\frac{\pi}{3}$ , -c. The magnitude of the required part (whother greater or less than 90°) is determined by placing their proper algebraical signs over the known years, and

also when two angles or sides come together on the same side of the equation a negative sign before them. The three signs thus on one side of the equation must produce the same result (positive or negative) as the sign of the other side.

(iii.) Oblique-angled Triangles On account of the property of plane triangles that the three angles of every such triangle are equal to two right angles, their solution is much simpler than that of spherical triangles where the sum of the three angles is not definite, but varies from two to six right angles. But an analogy exists between the fundamental formulæ of plane triangles and the corresponding ones of spherical triangles, which may serve to facilitate the latter being remembered. In the following Table it will be observed that a side or a combination of sides in plane triangles is replaced by their sines in spherical triangles.

VI.	Method i.
	(1) $L \sin \frac{a}{2} = \frac{1}{2} \left\{ L \cos S + L \cos (S - A) + L \csc B + L \csc C \right\} - 10$
	or (2) L cos $\frac{a}{2} = \frac{1}{2} \left\{ L \cos(S-B) + L \cos(S-C) + L \csc B + L \csc C \right\} - 10$
	or (3) L tan $\frac{a}{2} = \frac{1}{2} \left\{ L \cos S + L \cos (S - A) + L \sec (S - B) + L \sec (S - C) \right\} - 10$
	And similarly for $-$ and $-$
	Method ii.  By polar triangle A' B' C'. See case i.

Triangle, Astronomical or Instantaneous.—In Nautical Astronomy the most important spherical triangle is that of which the angular points are the elevated pole of the heavens P, the zenith of the observer Z, and the body observed X; the sides being the polar distance of the body p (the complement of its declination d), the zenith distance of the body z (the complement of its altitude a), and the zenith-polar arc c, which corresponds to the co-latitude of the observer,

This triangle is often called the Astronomical Triangle, but I have suggested for it the term Instantaneous Triangle. This term prevents all confusion of ideas, and describes its nature with accuracy. The triangle is formed by a transitory combination of elements in three different systems of co-ordinates, two of which are co-axial or co-polar (admitting therefore the coincidence of one of their angles), and two mutually having, each, the pole of its primary situated on the secondary circle of the other (admitting therefore the coincidence of one of their sides). Thus the angle P belongs both to the great-circle system of co-ordinates Right Ascension and Declination and to the polar system of co-ordinates Hour-Angle and Polar Distance.

Again, the side c belongs both to the great-circle system of co-ordinates Azimuth and Altitude, and to the celestial measure of the terrestial co-ordinates Longitude and Latitude, viz. Time and the Elevation of the pole. We can imagine the different systems to be fixed for a moment and the points P and Z to retain their relative position. This can only be for a vanishing instant and therefore we call the triangle PZX the Instantaneous Triangle.

Triangulum Australe (L. "The Southern Triangle").—A constellation lying about half-way between Scorpio and the south pole. Trianguli Australis, mag. 2-2, NA.1896; R.A.16h 40m, Dec. - 68\*50

Tropics (Gk. τά τροπικά, from τρέπω, "I turn"). - The two parallels, one on the north and the other on the south side of the equator, whose latitude is equal to the sun's maximum declination (about 23° 27' N. and S.) The term was originally applied to the celestral parallels of declination of about 23° 27' N and S. Their positions go through small changes of long period. When the sun, after coming north, has attained his greatest northern declination, he "turns" towards the equinoctial again; and when, after going south, he has attained his greatest southern declination, he "turns" towards the equinoctial again. Hence the name Tropics; and as at the time this nomenclature was adopted the sun attained his greatest northern declination in the constellation of Cancer, and his greatest southern declination in the constellation of Capricorn, the Northern and Southern Tropics were respectively called the Tropic of Cancer and the Tropic of Capricorn. The tropics mark out the limits of the torrid zone, or that portion of the earth's surface over which the sun can be vertical during the year, dividing this belt from the temperate zones.

True. —An adjective used to qualify elements when referred to a common standard for comparison. Thus the centre of the earth is the imaginary common standing-ground whence the heavens are supposed to be viewed through a uniform medium, and to which all observations of the heavenly bodies, made at different parts of the earth's surface through the atmosphere, are reduced and referred for comparison and computation. Hence the "True Place" of a heavenly body is its projection on the celestial concave, the body being supposed to be viewed from the centre of the earth through a uniform medium; distinguished from the "Apparent Place." The epithet true, therefore, does not indicate the actual place of the body in space. but a standard position of its projection on the celestial concave, to which all other positions that its projection assumes, when seen from different spots on the earth's surface, may be referred and reduced. Similarly we have the "True Distance" of two heavenly bodies, distinguished from their "Apparent Distance." Again, the normal to the earth's surface is the direction to which we refer angles of elevation, and hence the point in which this line meets the celestial concave is designated as the "True Zenith," as opposed to the "Reduced Zenith"; and thus also the "True Latitude" of an observer is distinguished from the "Reduced Latitude." manner the meridian, being the common line to which we refer directions on the earth's surface, the "True Bearing" of an object, or the "True Course" of a ship, is an angle reckoned from the meridian, distinguished from the "Compass Bearing" and the "Compass Course."

Twilight (Sax. tweon-leoht, "doubtful light").—The atmosphere, by refracting the sun's rays, causes that body to be seen by a spectator on the earth's surface while yet in reality below his horizon.

But before the sun thus becomes visible, rays of light illuminate the atmosphere, which reflects and scatters them in all directions, and the result is that faint "doubtful" light which precedes the rising of the sun and follows its setting, called twilight. Twilight begins in the morning and ends in the evening when the sun is about 18" below the horizon; and its duration, therefore varies with the latitude, for the time which is required for the sun to rise through 18" vertically depends upon the inclination of its diurnal path to the horizon of the place, and is greater as this inclination is less, i.e. the higher the latitude. Twilight is the best time for observing altitudes of stars at sea, for then the horizon is in general clearly visible and distinctly marked.—See Illumination.

**Typhoon** (Gk. τυφώς, "a violent wind," which whirls up clouds of dust or must; from τῦφος, "smoke," "cloud").—This word is now specially applied to the revolving atorms of the Chinese seas.—See under **Storms**.

U.

u.—Of the letters used to register the state of the weather in the log-book, u indicates " Ugly threatening appearance of the weather."

Uranography (Gk. ούρανὸς, "heaven"; γράφειν, "to grave," describe"). -The science which deals with the mapping down of the celestial concave, representing the relative positions of the stars on a globe or on charts. Compare the terms geography, hydrography.—See Stars.

Uranus (Gk. obpards, "heaven").—The name now given to the planet revolving round the sun next after Saturn. It has also been called Herschel and Georgium Sidus.

Ursa Major (L. "The Grenter Bear") - The most brilliant constellation of the northern hemisphere consisting of easen principal stars. By the common people of most conntries this group is called " The Waggon," and sometimes " The Plough", in England it use been known as " ('harles's Wasa'" It is one of those constraint, as which, like Ursa Minor, Cassiopeia, and Diaco, in our labinde (51° N) never set, and therefore it can always be seen by us on a clear night. The four stars a, B, Y, 5, form a trapezium, the longest side of which contains a and &, y being in the opposite angle to a. next to 8 is affixed a scalene triangle, formed by the stars e 5. % The two stars 3 and a are called "The Pointers," as they point to the pole star; the pole star which represent the tail of the Bear. being thus found, the position of the pole itself may be toughty determined with the aid of the other star ( See Polaris )

Ursa Minor (L. "The Lesser Bear") -A constellation notable from its containing, at the end of the tail, the Pole Star In form ! is something like the tireater Beat, the trapezium of the one being adjacent to the triangle of the other. a l'eser Minoria or Poloni Stella, mag. 2.2; N.A. 1896, R.A. 15 21m, Dec - 88° 45 -6 Polaris.

٧.

▼ -Of the letters used to register the state of the weather if log book, V indicates " Visibility of Distant Objects, whether the cloudy or not "

Vane (Sex. Funa, Dut. Vana) .-

to showing the direction of the

2. A sight placed on instruments for taking observations of altitudes and distances, marking the direction from the eye to the object.

Variation of the Compass (L. variatio, "a changing".—
The angle which the position of the magnetic needle, undisturbed by local attraction or ship's influence, makes with the geographical meridian of the station. This term should be exclusively appropriated to the error which arises from the magnetic poles of the earth not coinciding with the poles of rotation. -See Magnetic Needle, and Compass.

Vega. - The proper name of the bright star a Lyra See Lyra.

Venus (named after the Roman goddess of beauty) -The most beautiful of the planets. It is one of the inferior planets, its orbit being next to that of the earth. In actual size Venus is a little less than the earth, but owing to its propinquity to us, its apparent diameter is sometimes as much as 62". In consequence of its proximity to the sun it shines with a very bright light, but as seen from the earth this brightness varies in a remarkable manner. The change is due partly to the change of apparent magnitude of the disc from change of distance, partly to the varying ratio of the visible illuminated area to its whole disc, for it presents phases like those of the muon. The light is of a bluish tinge. The transits of Venus across the sun's disc are important astronomical phenomena, as they afford the best means of determining the sun's parallax and consequently the dimensions of the planetary system. To the navigator the body is chiefly important as serving, in a pre-eminent manner, the ordinary purposes of bright stars, such as determining the latitude, and by its lunar distances furnishing the means of obtaining the longitude

deserves especial notice, as it can often be observed during the daytime; it was called by the Greeks *Hesperus*, the "evening," and *Phosphorus*, the "morning" star. Symbol ?.—See **Planets**.

Vernal Equinox (L. vernālis, " pertaining to the spring," ver).—Relatively to the northern hemisphere, the Vernal Equinox is that date when the sun crosses from the south to the north of the equinoctial; about March 20th.—See Equinoxes.

Vernal Equinoctial Point.—Relatively to the northern hemisphere, the Vernal Equinoctial Point is the intersection of the ecliptic by the equinoctial, at the point where the sun crosses from the south to the north of the equinoctial. It is more generally called "The First Point of Aries".—See Equinoctial Points.

Vernier (named after the inventor Pierre Vernier, 1631).—An index for reading off the graduated scale or limb of an instrument by which aliquot parts of the smallest spaces into which the scale or limb is divided are measured. It consists of a piece similar to the scale or arc to be read, along which it alides. The length of this piece is made such as to include exactly some particular number of divisions of the scale; it is then divided into a number of equal parts, differing by one from the number of divisions in that part of the scale with which it co-incides. There are hence two forms of vernier, according as the number of divisions in it is one less (fig. 1) or one greater (fig.2) than in the corresponding length of the scale. Now, if the two extremities of the vernier be made to coincide with certain lines of graduation of the scale, then it is evident that none of the intermediate lines of the vernier will coincide with those of the scale. The first division of the vernier will exceed or fall short of the first of the intermediate divisions of the scale by a certain space, the

 $\frac{l}{n+1}$  in length. The difference therefore between the length of the divisions on the vernier and on the limb is

$$\frac{l}{n}-\frac{l}{n+1}=\frac{l}{n(n+1)}.$$

When the second kind of vernier is used, the length l of the limb is divided into n-1 parts, each of which will be  $\frac{l}{n-1}$  in length. The difference therefore between the length of the divisions on limb and on vernier is

$$\frac{l}{n-1}-\frac{l}{n}=\frac{l}{(n-1)n}.$$

The first kind is the form originally proposed by the inventor; it has the advantage of the greater size and consequent clearness of its divisions, but it has to be numbered backwards or in a direction contrary to that of the limb of the instrument.

It would be convenient to have distinctive names for the two kinds of verniers. From their size, relatively to a portion of the limb containing the same number of divisions, they might be distinguished as the Greater and Less Verniers. From the direction of their graduation they might respectively be named the Reverse and Direct Verniers. From their position relatively to the zero point when advanced along the limb, the two kinds might be termed Following and Preceding Verniers. The minuteness of the possible reading is known as the Degree of Accuracy.

A vernier of the first kind is that which is generally attached to the scale of an ordinary barometer. The barometer scale (fig. 1) is divided into inches and tenths; and the vernier, being in length \{\cdot\} of an inch and divided into ten equal parts, measures hundredths of an inch.

The vermer used for scientific barometers is of the second kind, and in general twenty-five vermer spaces equal twenty four of the scale spaces, which are each half a tenth, or five hundredths of an inch; therefore the difference between one of the vermer and one of the scale is two tenths of a hundred, or two thousandths of an inch. Thus in the marine barometer, reading 002 of an inch, the short divisions on the scale correspond to 05 of an inch, the long divisions on the vermer to 01, and its short divisions to 002 of an inch.

The himb of the sextant, and of similar astronomical instruments, is read by a vermer of the second kind (ng. 2). Suppose the limb to be cut to a third part of a degree, or 20', then, if the length of the vermer be equal to 19 of these divisions, and is divided into 20 equal parts, by its means we are enabled to read off to of each division of the limb, or to measure angles truly to 1'. This is the simple form of the vernier. In instruments for measuring angles it is convenient that the vernier should be divided into 60 equal parts, so as to enable us to read off to the same number of seconds as the limb is graduated in to minutes. This could be effected by making it in length equal to 59 divisions of the limb; but then, if the limb is highly graduated, the cutting would be minute, and the reading by the vernier not clearly distinguishable. The difficulty is obviated as follows: The vernier is made in length equal to \( (n × 60) 1 \) divisions of the limb (where n is an integer), but still dividing it into 60 equal parts instead of  $(n \times 60)$ . Thus, let the limb be graduated to 10'; take n=2, then the length of the vernier will be 119 of the divisions of the limb (10 each). Now if the vernier were divided into 120 (2 × 60) equal parts, it would enable us to read to Tio of 10'; but this is unnecesmry and inconvenient. It is therefore divided into 60 equal parts only, and embles us to read to als of 10', or to 10'.

Vertical Circles (L. vertex, "the top" or "crown," from verto, "to turn"). Great circles of the celestial concave which pass through the vertex of the visible hemisphere, and are therefore perpendicular to the horizon. They are also called "Circles of Altitude," because altitudes are measured on them, and "Circles of Azimuth," as marking out all points that have the same azimuth.—See Co-ordinates for the Surface of a Sphere.

Vertices of Great Circle.—The two points of highest latitude N. and S. on the great circle passing through two given places, such places not being both on the same meridian or on the equator. Each vertex is 90° from the points where the great circle crosses the equator.

Virgo, Constellation of (L. "The Virgin").—The sixth constellation of the ancient zodiac, lying between Leo and Libra. It contains a very brilliant star, a Virginis called also Spica, which may be found by drawing a line from Dubhe through Cor Caroli, and producing it to a little more than the same distance; or it may be recognized as forming an equilateral triangle with Arcturus and  $\beta$  Leonis, of which it is the southern angle. Mag. 1.2 N.A. 1896, R.A. 13h 20m. Dec.  $-10^{\circ}$  37'.

Virgo, Sign of.—The sixth sign of the ecliptic, including from 150° to 180° of longitude. Owing to the precession of the equinoxes, the constellation Virgo is no longer in the sign of this name, the constellation Leo having taken its place. The sun is in Virgo from about August 23rd to about September 23rd. Symbol m.

Visible Horizon.—(1) The circle of the celestial concave which divides the visible from the invisible portion of the heavens (2) The circle of the terrestial sphere which divides the visible from the invisible portion of its surface.—See Horizon.

Vulgar Establishment of the Port.—The establishment of the port—i.e. the time of high water at the full and change of the moon at the given port—determined roughly by observation on the day of full or change.—See under Tide.

## W

w. -Of the letters used to register the state of the weather in the log book, w indicates " Wet Dem."

Wake —The wake of a ship as she moves through the sea is the transient impression she leaves on the surface caused by the meeting again of the divided waters. It indicates her actual path through the water, which is not always in the same line with that of her keel. The angle between the two lines measures the amount of leavay.

Wave (Sax may) The oscillation caused in a fluid by a motion perpendicular to its surface. The alternate rising and falling causes the appearance of a transfer of the body of the fluid in the direction in which the wave is propagated, though no such transfer actually takes place. The action may be illustrated by the fluitering of a flag, the shaking of a sail, or the appearance of a field of standing corn when a breeze passes over it.

Wave, Height of.—The perpendicular rise of the vertex of the wave or "crest' above the lowest part of its depression or "hollow,"

Wave, Length of -The nonzontal distance between two adjacent crests, or two adjacent hollows

Wave, Velocity of. The rate at which the crest moves forward; it is the length of the wave divided by the interval any phase takes to pass through the length.

Weather-glass.—This term is usually applied to the barometer, which by its rising and falling indicates in a general way the But a perfect weather-glass properly consists of impending weather. -a Barometer, which shows changes in the pressure or tension of the atmosphere; a Thermometer, which shows the changes in the tempature; and a Hygrometer, which shows changes in the moisture of the air. By combining these several particulars, the state of the air is known, and hence is inferred the character of coming weather. The following are the fundamental rules for the indications of the weather-glass in any latitude. Rise of barometer for cold, dry, or less wind (except wet from cooler side); fall of barometer for warm, wet, or more wind (except wet from cooler side). Thus, in northern latitudes, if the barometer has been about its ordinary height, say nearly thirty inches at the sea-level, and is steady, or rising, while the thermometer falls, and dampness becomes less, north-westerly, northerly, or north-easterly wind—or less wind—less rain or snow may be expected. On the contrary, if a fall takes place, with a rising thermometer, and increased dampness, wind and rain may be expected from the south-eastward, southward or south-westward. Exceptions. -When a northerly wind with wet (rain, hail, or snow) is impending, the barometer often rises on account of the direction of the coming wind alone. For more particular rules, with their exceptions, the reader is referred to Rear-Admiral Fitzroy's "Barometer Manual," issued by the Board of Trade.

Weather Notation.—To register the state of the weather the annexed system of letters was devised by Sir Francis Beaufort, and used by him in his log of H.M.S. Woolwich, 1805. It has been adopted in the Royal Navy by Admiralty order, dated December 28, 1838:—

```
b denotes Blue Sky-whether with clear or hazy atmosphere.
```

- c ,, Cloudy—i.e. Detached opening clouds.
- d , Drizzling Rain.
- f ,, Fog; f Thick Fog.
- g ,, Gloomy Dark Weather.
- h .. Hail.
- 1 ,, Lightning.
- m ,, Misty or Hazy—so as to interrupt the view.
- O ,, Overcast—i.e. The whole sky covered with one impervious cloud.
- p ,, Passing Showers.
- q ,, Squally.
- r ,, Rain-i.e. Continuous Rain.
- 8 ,, Snow.
- t .. Thunder.
- u ,, Ugly threatening appearance of the Weather.
- v ,, Visibility of Distant Objects—whether the sky be cloudy or not.
- w ,, Wet Dew.
- Instead of this mark, some meteorologists are accustomed to repeat a letter to augument its signification. Thus, ff, very foggy; rr, heavy rain; rrr, heavy and continued rain.

By the combination of these letters all the ordinary phenomena of weather may be recorded with certainty and brevity. Examples—bcm, Blue sky, with detached opening clouds, but hazy round the horizon; gy, Gloomy dark weather, but distant objects remarkably visible; qpdlt, very hard squalls, and showers of drizzle, accompanied by lightning, with very heavy thunder.—See Wind, Force of.

West Point of the Horizon.—The west is the cardinal point on that side of the horizon where the heavenly bodies set. The East and West Points are the points in which the prime vertical intersects the horizon, the equinoctial also passing through them, and they are the origins from which amplitudes are reckoned. They are the poles of the celestial meridian.

Westing.—The distance, expressed in nautical miles, a ship makes good in a west direction; it is her departure when sailing westward. Opposed to *Rasting*.

Wind, Aberration and Acceleration of.—The change in the apparent direction of the wind, in consequence of the motion of the observer, we call the aberration of the wind. The change in the apparent rate of the wind, in consequence of the motion of the observer, we call the acceleration of the wind; it is negative, and appears as retardation when the directions are not opposed.

For explanation of the terms, see under Aberration and Acceleration.

Example—A north wind is blowing at the rate of 10 knots an hour and two steamers cross, one on a west and the other on an east course, the former going 12 and the latter 8 knots an hour. They would apparently experience, respectively, a N.W. and a N.E.N. wind, a difference of 8 points. And so for the rates: the former would experience a wind blowing 16, and the latter a wind blowing 13 knots.

Every seaman is familiar with these phenomena, and practically takes them into account for his own immediate requirements; but the subject has not been fully recognized in a systematic manner for the general interests of nautical meteorology. Experience teaches the seaman to estimate the true direction and real force of the wind

by the indications of the tops of the waves or of the lowest clouds, which he instinctively takes into account; also from the known behaviour of his ship under given conditions.

The following exact method of deducing the true direction and force of the wind, from its apparent direction and force, combined with the course and speed of the ship, will be of interest to the scientific keeper of a meteorological log. Our data are:

The compass course of the ship through the water, NAC;

The rate of the ship AU ( r);

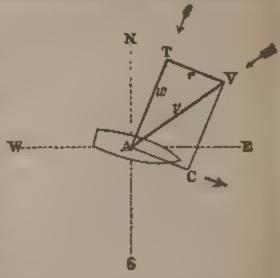

The apparent compass direction of the wind, as indicated by a vane, VAN;

The apparent velocity of the wind, estimated by an anemometer, VA (=0).

We have to find :

The true direction of the wind TAN; and
The true velocity of the wind
TA (=w).

Complete the parallelogram ACVT; then knowing the angle NAC, we may, for simplicity, refer all the directions to AC. In the triangle TVA, the angle V and the two sides r and v are known; to determine W and w:

(I.) To find the aberration TAV (=A), and thence the true direction of the wind TAN;

$$\operatorname{Tan} \frac{1}{2} (\mathbf{T} - \mathbf{A}) = \frac{v - r}{v + r} \cdot \cot \frac{\mathbf{V}}{2}$$

$$\frac{1}{2} (T+A) = \frac{1}{2} (180^{\circ} - \nabla)$$
Hence  $A = \frac{1}{2} (T+A) - \frac{1}{2} (T-A)$ 

And True Direction = Apparent Direction - Aberration.

(II.) To find the true velocity of the wind TA = (w)

$$\frac{w}{r} = \frac{\sin V}{\sin A} \text{ or } \frac{w}{v} = \frac{\sin V}{\sin T}$$
The acceleration (a) =  $v - w$ .

Wind, Direction of.—The direction of the wind is named after the point of the compass from which it blows.—See under Direction.

Wind, Force of.—To register the force of the wind the annexed system of figures was devised by Sir Francis Beaufort, and used by him in his log of H.M.S. Woolwich, in 1805. It has been adopted in all her Majesty's ships by Admiralty order, dated December 28, 1838.—See Weather Notation.

O denotes Calm.

12 , Hurricane ... to which she could! No cunvas.

Winds, Trade. Winds which, blowing perpetually in the same constant direction (north-easterly in the northern, and south easterly in the southern hemisphere), are subservient in a peculiar manner to the purposes of navigation and trade. These important currents of the atmosphere are the result of a combination of two causes First, the unequal exposure of the earth's surface to the sun's rays causes the air over the equatorial regions to be unduly heated and rarified; it consequently ascends, while the cooler and denser air from the regions more polar rushes in along the earth's surface to supply its place, the heated air being carried along the higher strata towards the poles. Hence, if unmodified by any other cause, two counter carrents in each hemisphere would be formed in the direction of the meridian. But, secondly, the equatorial portion of the earth's surface has the greatest velocity of rotation, and all other parts less in the ratio of the radii of the parallels of latitude to which they correspond. A portion of air, therefore, coming from the polar to the equatorial regions revolves more slowly than the parts of the earth over which it in succession arrives, and it will consequently lag behind and drag upon the surface in a direction contrary to the earth's rotation - i.e. from east to west. Thus the currents which, but for the earth's rotation, would be simply northerly and southerly winds, acquire from this cause a relative direction towards the west, and assume the character of permanent north-easterly and south-As these two currents approach the equator, their easterly winds casterly tendency is generally diminished by the friction of the earth and when they meet at the equator their northerly and southerly

directions mutually destroy each other; hence an equatorial belt of comparative calm which separates the belts of the north-easterly and south-easterly trades. The trade-winds are modified in direction and intensity by the neighbourhood of continents, and vary in position with the seasons.

Windward Sailing.—When a ship has a foul wind she has to work to windward, making her destination by means of tacking. Windward sailing is therefore a case of traverse sailing, in which the characteristic inquiry is, what is the most advantageous time for tacking? Supposing the wind to remain constant in direction, the general principle is to endeavour to near the destination from instant to instant. In order to do this the destination must always be kept in the wind's eye, a condition which would necessitate continued tacking. This being practically impossible, the question resolves itself into determining the practical limits for the application of the theoretical principle. A ship nears the destination fastest on that tack on which she looks up hest for it; she should therefore stand on each tack as long as this continues to be the case, and then go about. The destination is above supposed to be fixed, as in the case of a port; but it may be another ship in motion, as in chasing. Chasing is a subject belonging to sea tactics, and was of great importance before the introduction of steam. In windward sailing, the position of the great circle is of the greatest importance. A wind which appears to be directly ahead when viewed in connection with the rhumb, may not be so with reference to the great circle; and as the great circle is the shortest path of the ship to her destination, that tack will be chosen that lies nearest to it, and persisted in as long as, judged by the same standard, it continues to be the most favourable. In short, in windward sailing tacking ought to have reference to the great circle, and not to the rhumb.—See Sailings.

Winter Solstice — Relatively to the northern hemisphere, the winter solstice is the period of the year when the sun attains his greatest southern declination—about December 21st. — See Solstices.

Y.

Year.-Generally-The period in which the earth makes a revolution in her orbit round the sun, as indicated by the corresponding apparent revolution of the sun in the ecliptic. But more particularly Some point must be taken to mark its commencement and period, which we call the "point of definition," and the choice (as this point may be fixed or have a proper motion of its own) gives rise to a distinction of several kinds of years which differ from each other slightly in length. (1) If a fixed star be taken as the point of definition, we have the Sulereat Year. (2) If the first point of Aries (which has a slow retrograde proper motion of about 50 22" annually) be taken as the point of definition, we have the Solar, Equinoctial or Tropical Year. (3) There is also what is called the Anomalistic Year, which is the period between two successive returns of the earth to the perthelion of her orbit, a point which has a direct proper motion of 11 25" annually. The anomaly (6k. dv, "not," dualds, "even"; "irregularity") of a planet is its angular distance from the perihelion of its elliptic orbit as seen from the sun, and it is so named because the angular motion about the sun in the focus is not uniform. The relative lengths of the three years will be-

Sidereal: Tropical: Anomalistic = 360°: 360° 50 22": 360° + 11-25"

The tropical year having been found, we have the following values, in mean solar time,

Sidereal year  $= 365^{\circ}256374$  days  $= 365^{\circ}$ 

Year, Sidereal (L. sidus, "a star")—The period in which the earth makes a revolution in her orbit with reference to the fixed stars. ·Substituting the sun's apparent motion in the ecliptic, the sidereal year is the interval between his leaving a fixed point in the celestial concave, such as a fixed star, and returning to that point again. sidereal year consists of 365d 6h 9mlls, reckoned in mean solar time, and of 366d 6h 9m lls, reckoned in sidereal time. The reason of this difference is that the sun's apparent annual motion among the stars is in a direction contrary to the apparent diurnal motion of both sun and stars. The effect is the same as if the sun lagged behind the stars in his daily course, and when this has gone on for a whole year, he will have fallen behind them by a whole circumference of the heavens—i.e. in a year the sun will have made fewer diurnal revolutions by one than the stars. The same interval of time, therefore, that is measured by 366d 6h, etc, of sidereal time will be measured by 365d 6h, etc., of mean solar time.

Year, Solar, Tropical, or Equinoctial.—The interval in which the sun in his apparent motion makes a complete revolution of the ecliptic, thus describing 360° of longitude. The first point of Aries being the origin, the solar year is defined to be the period between the sun leaving the first point of Aries and returning to it again. This year is the period of the revolution of the seasons, which are determined by the apparent passage of the sun across the equinoctial, and his alternate stay in the northern and southern hemispheres, where the turning-points in his course are the tropics. The period is thus called the Tropical Year with reference to the solstices when the sun describes his diurnal circle of the tropics; it is also called the Equinoctial Year with reference to the equinoxes when the sun crosses the line; it is likewise called the Solar Year with reference to the sun's apparent motion in the ecliptic. In the sidereal

period, or year, the earth makes a complete revolution of the heavens, and the sun appears to do so, but not so in the tropical year. The vernal equinoctial point, owing to the conical motion of the earth's axis, retreats on the ecliptic and meets the advancing sun somewhat before the whole sidereal circuit is completed. The precession for the year 1897 is 50.2632", and this are the sun describes in 23.95. By so much shorter then is this solar year than the sidereal period. The tropical year is a compound phenomenon depending chiefly and directly on the annual revolution of the earth round the sun, but subordinately also, and indirectly, on its rotation on its own axis, which occasions the precession of the equinoxes. The tropical years vary in length owing to the motion of the first point of Aries not being uniform, and the sun's apparent motion being subject to irregularities.

Year, Mean Solar, or Mean Tropical.—The solar or tropical year has been defined as the interval which elapses between the sun, in his apparent motion in the ecliptic, leaving the first point of Aries and returning to it again. But the motion of the first point of Aries is not uniform, and the sun's motion in the ecliptic is from year to year subject to irregularities; hence solar years vary in length. An average of a long succession of solar years gives an approximation to the mean solar year. By a comparison of observations it was found that the sun had described 36000° 45′ 45″ of longitude in 36245 days mean time. Taking our average from this lapse of time, the length of the mean solar year=

 $360^{\circ} \times 36,245^{\circ} = 365^{\circ} 5^{\circ} 48^{\circ} 51.6^{\circ}$ 

The latest value obtained is about 365d 5h 48m 48s.

Year, Civil.—The year used for practical purposes should consist of an integral number of days, which the mean solar year does

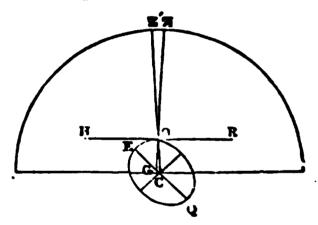

not. As an equivalent to a series of actual mean solar years, a succession of civil years, some consisting of 365 and others of 366 days each, has been established by the regulations of the calendar: the former are called *Common Years*, the latter *Bissextile* or *Leap Years*.—See Calendar.

Z.

Z.—The letter Z is sometimes used in log-books to denote haze.

Zenith (Arabic).—The superior pole of the celestial horizon. It is the point of the heavens vertically over a spectator's head—i.e. the

point in which the normal to the earth's surface at the station of the spectator, produced into space, meets the celestial concave. If the earth be considered a sphere, the normal will always pass through its centre, but on the spheroid

this is not the case. When, therefore, we take into account that the earth is in reality an oblate spheroid, we must distinguish between the true and the reduced zenith. The True Zenith is the point in which the normal to the earth's surface at the station of the spectator, produced into space, meets the celestial concave; the Reduced Zenith is the point in which the line joining the earth's centre and the station of the spectator, produced into space, meets the celestial concave. Thus let O be the station of the observer on the earth's surface, HR his horizon; OG the normal at O, and OC the semi-diameter passing through O, meeting the plane of the equator EQ respectively in G and C; let GO produced meet the celestial concave in Z, and CO produced meet it in Z'. Then Z is the true, and Z' the reduced zenith of the station O. They coincide at the poles, and on

the equator. The point diametrically opposite to the zenith is the nadir, which is the inferior pole of the horizon. —See Zenith and Nadir.

Zenith and Nadir (Arabic).—The poles of the celestial horizon. The Zenith is the superior pole, or the point of the heavens vertically over a spectator's head; the Nadir is the inferior pole, or the point of the heavens vertically under the spectator's feet.

Zenith Distance.—The angular distance of a point in the celestral concave from the zenith. It is the complement of its altitude above the horizon.

Zenith Parallels.—A name proposed for the circles of the celestral sphere corresponding to the jurallels of position on the terrestral sphere.—See Position, Parallels of.

Zenith Sector.—A shore instrument for measuring with great accuracy the zenith distance of the stars which pass the meridian near the zenith. Bradley constructed one when discovering the aberration of light and the nutation of the earth's axis. The zenith sector is applied in trigonometrical surveys for determining the difference of latitude of two stations.

Zenith polar Arc.—In the Instantaneous Triangle, the side joining the zenith and the pole; it is the celestial arc corresponding to the collatitude on the terrestrial sphere.

Zero (It.).—The term generally used to indicate the point of a scale from which the graduations commence. Thus,—the zero on the limb of a sextant is where the index should point when the index-mirror and horizon-mirror are parallel; the zero on the scale of a Réaumur and of a Centigrade thermometer is the freezing point of water; the zero of Fabrenheit's scale is obtained by the temperature

produced from a mixture of salt and snow. The readings of a scale are reckoned plus in one direction from the zero point, and minus in the contrary direction.

Zodiac (Gk. o judiands, from judicor, the diminutive of juor, "an animal").—That region of the heavens within which the apparent motions of the sun, moon, and all the most conspicuous of the planets. -those known to the ancients-are confined. By continued observation we may map down the apparents paths of these several bodies, just as the course of a ship is marked out by pricking off its place from day to day. It was thus found that the apparent path of the sun is a great circle inclined to the equinoctial at an angle of about 23° 27', to which the name "ecliptic" was given. Again, the apparent paths of the moon and of all the known planets were found to be spiral curves of more or less complexity, and described with very unequal velocities in their different parts. These bodies were observed, however, to have this in common, that the general direction of their motions is the same with that of the sun-viz. from west to east, contrary to that in which both they and the stars appear to be carried by the diurnal motion of the heavens, and moreover, that they cross and recross the ecliptic at regular and equal intervals of time, never deviating from the ecliptic on either side more than 8° or It is this zone of about 17° broad, having the ecliptic running along its middle, which was named the zodiac. Before the discovery of the asteroids, the zodiac restricted to the above limits formed the zone of the moving bodies of the heavens. But the orbits of many of the asteroids have a very considerable inclination to the ecliptic-Pallas nearly 35°—so that the significance of the zone of the zodiac is now, except in the most general sense, all but obsolete. The term zodiac is derived from the fact that the constellations of this zone

were anciently figured as "animals." Its circuit was divided into twelve equal parts, the "sign" or symbol of each being taken from the constellation with which it then coincided. They are as follows:-

## KORTHERN SIGNS.

77	Amina	. the Ram.
_	42 7 3 5 6 6	. LILE LIGHTIL

Cancer, the Crab.

Taurus, the Bull,

Leo, the Lion,

Gemini, the Twins.

Virgo, the Virgin.

## SOUTHERN SIGKS.

Libra, the Balance.

by Capricornus, the Goat.

Scorpio, the Scorpion. 領

# Aquarius, the Water-bearer.

Nagittarius, the Archer.

\* Pieces, the Fishes.

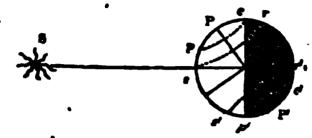

These constellations, however, do not cover the same parts of the ecliptic that they formerly did in consequence of the retrograde motion along the ecliptic, of the first point of Aries, or vernal equinoctial point, from which its divisions are reckoned. Hence the necessity of distinguishing between mgns of the ecliptic or rodiac and the constellations of the zodiac, the former being purely technical subdivisions of the celiptic, of 30° each, commencing from the first point of Aries.

-See Chart illustrating Lunar Distance Bodies.

Zone (Gk. Sáry, "a belt"). - A zone of a sphere is the portion of its surface included between two parallel circles,

Zones of the Earth.—In consequence of the obliquity of the scriptic, the surface of the earth is naturally divided into five zones or belts by the parallels of latitude called the Tropic of Cancer or (about 23 27 N., the Tropic of Capricorn ar (about 23 27 S.), the Arctic Circle pr (about 66° 33 N ) and the Antarctic Circle pe' (about 66° 33' 8) When the sun is in either solstice, he will be in the zen th of some place situated in one of the tropics. Thus are these parallels defined, and they are, therefore, the parallels of latitude of about 23

27' N. and S.; they bound a zone of about 46° 54' in breadth. every year the sun is at noon close to, if not actually in the zenith of every place in this zone; it is consequently the region of the greatest heat, and is hence called the Torrid Zone, Again, when the sun is in either solstice it

Twice

enlightens the pole on that side of the equator, and shines beyond it through an arc Pc, equal to the obliquity of the ecliptic (about 23° 27'); at the same time the opposite pole and the like extent of surface are enveloped in darkness. Within these zones (Ppc, P'p'c') during one; portion of the year (longer or shorter according to the distance from the pole) the sun does not dip below the horizon, and during another! portion of equal duration never rises above it in his diurnal revolution. As the sun's rays strike the earth's surface very obliquely in the polar; zones, their temperature is very low, and they are hence called the Frigid Zones, North and South. Between the torrid zone and the frigid zones are two other zones, over no part of which the sun is ever vertical, but where he is seen to rise and set every day throughout the year; the temperature of these two belts is consequently intermediate between that of the torrid and frigid zones, and from this circumstance they are named the Temperate Zones, North and South We must bear in mind, however, that owing to the different distribution of land and sea in the two hemispheres, zones of climate are not co-terminal with zones of latitude, and the above nomenclature is only to be accepted in a general sense. - See the figure under Seasons. ら グンニタ
